EDITOR-IN-CHIEF

Nima Rezaei gained his medical degree (MD) from Tehran University of Medical Sciences and subsequently obtained an MSc in molecular and genetic medicine and a PhD in clinical immunology and human genetics from the University of Sheffield, UK. He also spent a short-term fellowship of pediatric clinical immunology and bone marrow transplantation in the Newcastle General Hospital. Professor Rezaei is now the full professor of immunology and vice dean of International Affairs, School of Medicine, Tehran University of Medical Sciences, and the co-founder and head of the Research Center for Immunodeficiencies. He is also the founding president of Universal Scientific Education and Research Network (USERN). Prof. Rezaei has already been the director of more than 100 research projects and has designed and participated in several international collaborative projects. Prof. Rezaei is the editor, editorial assistant, or editorial board member of more than 40 international journals. He has edited more than 50 international books, has presented more than 500 lectures/posters in congresses/meetings, and has published more than 1100 scientific papers in the international journals.

FOREWORD

It is a great honor to be asked to introduce, with this foreword, the *Encyclopedia of Infection and Immunity*. This work will be read and enjoyed by many students, both graduate and postgraduate, including clinicians, laboratory practitioners, and scientists. Many colleagues have contributed to this important work, with over 230 original chapters assembled in sections and listed alphabetically. I offer my warm congratulations to the editors of this book, for soliciting a wide body of expertise and assembling it in a form that gives so much pleasure and information to the reader.

For those of us who work in the field of infection and immunity, the last two years have been exceptionally challenging. At the current time we are 22 months into a major pandemic caused by a novel coronavirus and its variants, and worldwide, sadly, there have been many hospitalizations and deaths. Clinicians and scientists in our field have been working flat out, caring for patients, generating or utilizing diagnostic tests, generating new knowledge in immunity to coronaviruses, or discovering, testing, and deploying new vaccines. Public Health practitioners have organized our medico-social responses to limit transmission and deal with the consequences of infection. Behavioral scientists have transformed our approach to informing the public, getting the best possible outcomes from effective communication. Governments have learned the danger of ignoring the expertise of scientists, and in many countries, the public look upon clinicians and scientists with gratitude and respect. It is a testament to the advancement of infection and immunity science that the genome of the virus was sequenced within a few weeks of COVID-19 emerging, and that within 12 months, the first trials of novel vaccines had been completed. These vaccines included some with exceptionally novel technologies, including the RNA vaccines and the viral-vectored vaccines.

Underpinning the academic agility of students and practitioners in Infection and Immunity is the universal strength of sound education. Readers of this book will be seeking the knowledge they need for a comprehensive understanding of infectious disease and immunology. We work in a fascinating discipline. Our field is unique in that pathogenesis involves at least two sets of genomes—on the one hand the microbe, and on the other, the host. The microbial genome programs its microenvironment to enable acquisition of and residence in a niche for sufficient time to replicate and further disseminate to other hosts. The human genome has evolved to tolerate and contain a wide range of symbionts and pathobionts, with highly sophisticated immune decision-making at the cellular level, but to respond to invading species with an elaborate coordinated repertoire of innate and acquired immunity. The complex conversation between many different microbes and the human host generates a wide range of disease phenotypes. This makes the job of an infectious disease physician so challenging but at the same time so fulfilling.

Our field is enriched by the many scientists and clinicians who are willing to share their experience with their peers and students. This book reflects the great variety of knowledge that has emerged over centuries of inquiry and endeavor, and I believe you will be rewarded by using it as one of your reference sources.

Robert C. Read

Editor-in-Chief, Journal of Infection

Professor of Infectious Diseases and Consultant Physician

University Hospital Southampton, United Kingdom

PREFACE

Although infections have been one of the most important health threats since centuries ago, the mechanisms of human defense against infections have been unclear until last century. The scientific world has remarkable progresses in the field of immunology during recent decades. Indeed, the novel discovery of genes related to different pathogens has enhanced our knowledge about the immune system. Understanding different pathogens and the immune mechanisms promote diagnostic strategies and design more efficient therapeutic agents.

Encyclopedia of Infection and Immunity is a comprehensive text, which covers topics not only on basic immunology and microbiology but also on clinical immunology and infectious diseases. Section 1 focuses on the immune system, while Section 2 describes the interaction between pathogens and immunity. Bacteria, viruses, fungi, protozoan parasites and helminths, and insect and mites are explained in Sections 3–6, respectively. Section 7 discusses the clinical infectious disease challenges, whereas clinical immunology is covered in Section 8. Laboratory tests and treatment protocols are the main focuses of Sections 9 and 10, respectively.

Encyclopedia of Infection and Immunity is the result of valuable contribution of more than 400 scientists from many well-known universities/institutes worldwide. I would like to hereby acknowledge the expertise of all contributors, for generously devoting their time and considerable effort in preparing their respective chapters. I would also like to express my gratitude to Elsevier for providing us the opportunity to publish this Encyclopedia.

Finally, I hope that this comprehensive book will be of special value for researchers and clinicians who wish to extend their knowledge on infection and immunity.

Nima Rezaei, MD, PhD

CONTENTS OF VOLUME 3

Section 7: Clinical Infectious Disease, Edited by Federico Iovino

Respiratory Tract Infections: Bacteria <i>Victor Morais, Esther Texeira, and Norma Suárez</i>	1
Respiratory Tract Infections: Viruses <i>Florencia Ferrara and Norma Suárez</i>	13
Respiratory Tract Infections: Fungi <i>Victor Morais and Norma Suárez</i>	19
Respiratory Tract Infections: Parasites <i>Esther Texeira, Victor Morais, Marcia Rodriguez, and Noma Suárez</i>	27
Urinary Tract Infections: Virus <i>Lorenzo G Luciani and Daniele Mattevi</i>	32
Urinary Tract Infections: Fungi (<i>Candida</i> spp.) <i>Fitz Gerald Silao, Francisco Javier Alvarez, Florida F Taladtad, Toni Andrea Marie D Vilorio, and Per O Ljungdahl</i>	44
Urinary Tract infections: Urinary Schistosomiasis <i>Theresa N Chimponda and Takafira Mdlulza</i>	60
Bacterial Gastrointestinal Infections <i>Alberto J Martín-Rodríguez, Enrique Joffré, and Åsa Sjöling</i>	72
Gastrointestinal Tract Infections: Viruses <i>Mathew D Esona, Rashi Gautam, Preeti Chhabra, Jan Vinjé, Michael D Bowen, and Rachel M Burke</i>	82
Fungal Infections of the Gastrointestinal Tract <i>Laura W Lamps and Bobbi S Pritt</i>	107
Parasites of the Gastrointestinal Tract <i>Blaine A Mathison and Bobbi S Pritt</i>	136

Pharyngitis

Pharyngitis is a recurrent infection, both in children and adults. Most cases are caused by a virus but some of them can be of bacterial etiology. Group A β -hemolytic *Streptococcus* (GAS), known as *Streptococcus pyogenes*, is the mayor commonly identified bacterial cause of acute pharyngitis. GAS is estimated to be the cause of the United States 15–30% pediatric pharyngitis cases. Other less frequent bacterial pharyngitis agents include groups C and G β -hemolytic streptococci, *Fusobacterium necrophorum*, *Neisseria gonorrhoeae*, and *Corynebacterium diphtheriae*, among others (Arnold and Nizet, 2018).

GAS is a prominent human pathogen, that leads to more than 600 million cases of throat infections per year mainly pharyngitis, tonsillitis and on the skin, it causes non-bullous impetigo (Carapetis et al., 2005; Hurst et al., 2018). Invasive disease is an infrequent consequence of the infection, through which the organism reaches the bloodstream and can get access to deeper tissues, with high impact in terms of morbidity and mortality. GAS pharyngitis is most common in temperate climates and may peak in the winter due to the confinement of the favoring transmission through the respiratory route (Bessen et al., 2015).

The determination of different groups of GAS strains has been possible using the serology-based Lancefield classification scheme, based on the antiphagocytic M protein surface fibrils (Lancefield, 1959). The cell wall-associated M protein is attached to the peptidoglycan of the bacterial cell wall and encoded by the *emm* gene. Protective immunity to GAS is M type-specific. Recently, a sequence-based *emm* typing scheme was carried out, based on extensive nucleotide sequence differences at the 5' end of the *emm* gene. Currently, more than one hundred GAS strains types has been identified based on M and *emm* type. M protein is antiphagocytic, proinflammatory, and facilitates to mucosal adhesion. Its exerts its antiphagocytic effect by binding to complement control factors and other host proteins interfering with activation of the alternative complement pathway (Hurst et al., 2018).

The biological significance of *emm* pattern genotypes is that they are strong markers for preferred tissue sites of infection among GAS strains. The *emm* pattern A–C genotype indicates a statistically significant association with pharyngitis, while on the contrary *emm* pattern D isolates show a statistically significant association with impetigo (Bessen et al., 2015). Besides M protein, GAS strains express many virulence factors including, streptolysins, streptokinase, hyaluronidase, peptidoglycan, teichoic acid. Nucleases (DNase), but only antibodies to streptolysin O and S (ASO titers) are regularly measured in clinical practice (Hurst et al., 2018).

Clinical manifestations

GAS pharyngitis is transmitted via respiratory droplets after a short incubation period. The symptoms include fever and sore throat, erythematous pharynx, cervical adenopathy and, enlarged lymph nodes in the neck. The infection can also lead to the development of other manifestations and complications, such as Scarlet fever caused by the production of an erythrogenic toxin. It occurs when in addition to pharyngitis and tonsillitis a generalized erythematous rash occurs over the upper trunk and spreads to the extremities. Afterward, the rash begins to fade followed by fine desquamation, first on the face, and then progressing downward. The erythematous eruption produces bright red discoloration and then leads to desquamation of the tongue and later skin (Arnold and Nizet, 2018).

The different M types of GAS infection can trigger serious post infectious immune-mediated disorders, including post-streptococcal reactive arthritis, glomerulonephritis, and acute rheumatic fever. Additionally, molecular mimicry of M proteins can cause autoreactivity with heart, synovium, and brain tissue, causing damage to these tissues. Rheumatic fever is a classical autoimmune syndrome that can follow an episode of pharyngitis. It presents fever, polyarthritis, and carditis, with long-term cardiac damage and which is a notable cause of morbidity and mortality. Post-streptococcal reactive arthritis is more common than rheumatic fever and presents sooner (on average 10 versus 21 days) (Peters et al., 2017). The antigenic similarity of M protein's to the glomerular basement membrane causes glomerulonephritis. It results in the formation of an immune complex with complement activation and acute nephritis. Generally, this often happens in children within 2 weeks after skin infection, but it can occur early after the pharyngitis infection. The diagnosis is clinical, and patients usually exhibit haematuria and proteinuria (Peters et al., 2017).

Etiological diagnosis

The diagnosis of GAS pharyngitis is based on clinical signs and symptoms. However, to avoid unnecessary treatment with antibiotics in cases of viral infections, some guidelines indicate that confirmation of GAS, with either a throat culture or a rapid antigen detection test (RADT), is necessary. A throat culture is a standard for the diagnosis of GAS pharyngitis with a sensitivity of 90–95% and the disadvantage that results may take up to 48 or 72 h. Currently available RADTs have specificities of 95% with sensitivity between 70% and 90% (Ann Maes, 2011).

Treatment

There are alternative drugs for GAS infection because the pathogen is sensitive to the penicillin group. Otherwise, in patients with penicillin allergy, macrolides are frequently used for superficial infections. The optimization of the treatment in invasive disease cases is frequently a combination therapy using a penicillin group as well as a ribosome-acting agent to reduce toxin production (e.g. clindamycin, linezolid). Currently, a 10 days therapy is recommended for most syndromes of infection caused by GAS as pharyngitis, although long-acting macrolides (azithromycin) are administered for 5 days. Prophylaxis can be used in outbreak settings and is also administered to mothers and babies in the neonatal period if they are exposed to a person infected with invasive GAS (Peters et al., 2017).

Sinusitis

Acute sinusitis is an inflammation of the nasal mucosa and sinuses. Distinguishing between the common cold and sinusitis is difficult, and the distinction is often made according to symptom duration. Typical common colds are self-limited and last 7–10 days, whereas acute sinusitis has a duration of up to 4 weeks. Sinusitis can be caused by bacteria or viruses, and identification is one of the most important determinants of treatment. Bacterial causes of sinusitis include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* (Grief, 2013).

Clinical manifestations

Symptoms of acute sinusitis are similar to the common cold, including nasal congestion with discharge, facial pain over the sinuses, decreased sense of smell, and cough. A bacterial origin is generally suggested if the patient shows purulent nasal discharge, maxillary tooth or facial pain, fever, and if symptoms worsen after initial improvement.

Etiological diagnosis

Acute bacterial sinusitis can be clinically diagnosed if purulent nasal discharge, nasal obstruction, focal facial pain, headache, and fever are present and if symptoms persist beyond 7–10 days. Nasal endoscopy and culture of secretions are good tests, but unfortunately, they are complex techniques that should be performed by a specialist. Thus, they are only used for the diagnosis of chronic sinusitis (Grief, 2013).

Treatment

General treatment for sinusitis includes maintaining adequate hydration, applying warm facial packs to help with pain relief, eliminating environmental contaminant factors, sleeping with the head of the bed elevated, and avoiding extremely cold or dry air. In some cases, the use of intranasal steroids, analgesics, and saline nasal irrigation could be prescribed.

The type of antibiotic that should be used depends on the bacteria. Amoxicillin-clavulanate is the preferred empiric antimicrobial therapy. Other antibiotics that could be used include doxycycline or combination therapy with a third-generation oral cephalosporin (cefixime or cefpodoxime) plus clindamycin. Levofloxacin could be prescribed for children older than 8 years with a history of hypersensitivity to penicillin (Grief, 2013).

Epiglottitis

Infectious epiglottitis is an acute inflammation of the epiglottis or supraglottis and can lead to airway obstruction. In almost all cases, it is caused by the bacteria *Haemophilus influenzae* type b (Hib). Nowadays, this infection has become very rare in most countries. This is due to the universal vaccination against Hib, which majorly reduces the incidence of epiglottitis. However, epiglottitis continues to remain potentially life-threatening, and the security of the airway and antibiotic treatment should be established early to ensure the life of the patient (Pham et al., 2017).

Physiopathology

Hib colonizes the pharynx of healthy people, and mainly children, through respiratory transmission from close contact. Then Hib can penetrate the mucosal barrier and invade the bloodstream, causing bacteraemia. After this Hib can cause epiglottitis, sepsis, pneumonia, meningitis, and many other infections. Epiglottitis infection leads to acute onset of inflammatory edema that significantly reduces airway aperture. Edema rapidly progresses thus involving neighboring areas.

Other species that may cause epiglottitis are other *Haemophilus* strains, some *Streptococcus* strains, *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Pasteurella multocida* (Pham et al., 2017).

Clinical manifestations

In addition to edema of the epiglottis, patients exhibit stridor, dyspnoea, fever, and sore throat, among other symptoms. Acute epiglottitis may progress rapidly into life-threatening upper airway obstruction, mainly in children. In adults, symptoms tend to have a slower onset. Airway obstruction may occur by progressive cellulitis of the supraglottic area (Pham et al., 2017).

Diagnosis

Diagnosis of epiglottitis is not difficult because patients present a swollen and red epiglottis. Visualization of the posterior pharynx is the best way to confirm the diagnosis of epiglottitis. After securing airway blood cultures and epiglottic cultures, radiographs of the neck should be obtained, which can show the mass shadow resulting from the edema. Occasionally, bacterial epiglottitis could be misdiagnosed as laryngotracheobronchitis (croup). This occurs mainly in children and at the beginning of the illness; however, some symptoms and signs are common in both cases. Signs of upper airway obstruction such as drooling without coughing can help differentiate epiglottitis from croup (Pham et al., 2017).

Treatment

It is very important to secure the airways because intubation of the patient could be necessary in severe cases. Intubation is needed for less than 24 h in most cases. Most children can be extubated after 24 h of antibiotic therapy. Hospital treatment can last up to 3 days. Antibiotic treatment mainly includes cephalosporins like cefuroxime, ceftriaxone, and cefotaxime.

Some physicians administrate steroids to decrease the edema. It is important that close contacts (family, etc.) receive a prophylaxis treatment with an adequate antibiotic to avoid secondary infection (Pham et al., 2017).

Acute laryngitis

Acute laryngitis is included by many authors in the group of laryngo trachea bronchitis and it is known by the common term of croup. Croup is an inflammatory infection affecting the larynx, trachea, and bronchi.

Clinical manifestations

Croup frequently begins with a sore throat, along with fever, rhinorrhea and cough. This is followed by the appearance of characteristic symptoms such as hoarseness and non-productive cough which ends with inspiratory stridor (Grief, 2013). A radiograph of the neck can show subglottic obstruction.

Diagnosis

Croup is mainly caused by a virus but some bacterial species can also be responsible for the infection, such *Haemophilus influenzae* type B, *Mycoplasma pneumoniae*, *Corynebacterium diphtheriae*, *Moraxella catarrhalis*, and group A β -hemolytic *Streptococcus* (Caserta, 2015; Grief, 2013). The degree of severity of croup is evaluated by the Westley Croup score. This score includes the evaluation of stridor, chest wall retractions, air entry, cyanosis and level of consciousness (Bourayou et al., 2010; Johnson, 2009; Zafar et al., 2017).

Microbiologic diagnosis can be established through bacterial cultures from the pharynx or in some cases by rapid antigen detection. Radiographs of the lateral neck can be necessary to make a differential diagnosis of epiglottitis. Croup shows subglottic narrowing that is wider on expiration than on inspiration and a normal epiglottis, whereas epiglottitis shows a swollen epiglottis.

Treatment

There are various types of treatment depending on the severity of croup but in mild cases, the use of oral corticoids could be enough. However, in severe cases the use of nebulized epinephrine and dexamethasone is necessary and some cases require oxygen administration or intubation (Grief, 2013; Pham et al., 2017).

Given that almost all croup cases are caused by a virus there is no recommended empirical antibiotic therapy and so antibiotic treatment can vary depending on the bacterial agent.

Whooping cough

Whooping cough is an infection of the respiratory mucosa caused by infection with *Bordetella pertussis* or related members of the genus. The infection is highly contagious and is characterized by a paroxysmal cough.

Physiopathology

The initial step of the infection is the colonization of the ciliated epithelium of the bronchi and trachea. Then, the bacteria, produces a cytotoxin that paralyzes the cilia and leads to paroxysms of coughing as an alternative means of removing the increased mucus (Preston, 2012).

Clinical manifestations

The infection has several phases, starting with an incubation period of 1–3 weeks, which is followed by a catarrhal phase with a simple cough, rhinorrhea, increased lacrimation, conjunctival injection, and sometimes a low-grade fever.

After some days and up until a week, the catarrhal phase gives way to the paroxysmal phase, characterized by a paroxysmal cough. This cough consists of a series of uncontrollable expirations, followed by gasping inhalation that is responsible for the whooping sound. Each episode of coughing can be associated with cyanosis and vomiting. Between episodes the patient shows minor symptoms and usually does not appears to be ill. This phase can be extended for 4 weeks (Hewlett, 2012). The last phase is the convalescent phase where the patient presents a chronic cough, which can last from weeks to months (Hewlett, 2012).

Diagnosis

Owing to the characteristics of the cough attack, the diagnosis of whooping cough is usually made clinically. However, in cases of atypical or mild illness, a laboratory diagnosis could be necessary. In these cases, bacterial culture is the best choice and it has the highest specificity; bacteria can be serotyped and antibiotic susceptibility can be determined. Furthermore, *Bordetella* antigens may be detected in serum and urine in tests with specific antiserum. Further, polymerase chain reaction (PCR) is also available (Preston, 2012).

Treatment and prevention

The recommended antibiotic is a macrolide type, with the most common one being azithromycin. Potential alternatives are clarithromycin or erythromycin. Treatment reduces the severity of the illness if given before the paroxysmal stage. Moreover, it is important to eliminate the bacteria to reduce the exposure of contacts. This is a highly contagious illness so macrolide may also be given as a form of chemoprophylaxis for exposed individuals.

The best type of prevention is vaccination. A killed, whole cell vaccine and acellular pertussis vaccine, are available and are administered to infants and children in most countries (Hewlett, 2012; Preston, 2012).

Acute pneumonia

Pneumonia is a common inflammatory disease of infectious etiology which affects the pulmonary parenchyma. It can be caused by bacteria, viruses, fungi, or parasites. Pneumococcal infection is the leading etiology responsible for the incidence and mortality of lower respiratory infections among children and adults. *Streptococcus pneumoniae* are encapsulated, nonsporulating, facultative anaerobic, lancet-shaped gram-positive bacteria that reside in the human nasopharynx (Morais et al., 2019; Troeger et al., 2018). Several factors such as age, associated diseases, and the context in which the infection is acquired (community, residences, hospital), condition the frequency with which the various etiological agents cause pneumonia. Likewise, these factors influence the clinical symptomatology, radiological pattern, treatment selection, evolution, complications, and prognosis of the disease. Pneumonia is characterized by fever, variable respiratory symptomatology and the appearance of infiltrates in radiology. Therefore this entity involves clinical, radiological and evolutionary diagnosis (Torres and Rodriguez de Castro, 2020).

In the extreme ages of life, the incidence of pneumonia is higher than that in the rest of the population and it is in these patients that the consequences are more serious. Pneumonia represents a relevant problem in public health, both in asocial and economic context, which include high morbidity and mortality, high hospitalization rates, prolonged hospital stay, and high costs. In recent decades and considering the difficulty to establish the etiology of the disease in most cases, classifications have been used based on clinical characteristics and the affected population. According to the guidelines proposed by the American Thorax Association, three type of pneumonia can be established (Mandell et al., 2007; Metlay and Fine, 2003). The first type is community-acquired pneumonia (CAP), which is infection of the lung parenchyma produced by microorganisms acquired outside the hospital environment. As the reporting of CAP is not mandatory and only 20–50% of patients are hospitalized, its incidence is difficult to establish. CAP has a broad clinical presentation and causal agents. It is also a frequent cause of consultation in the emergency department, which implies that it causes significant burden on health care systems and their resources. Affected populations need to be differentiated according to age (children and adults over 65 years), comorbidities such as congestive heart failure (CHF) and chronic obstructive pulmonary disease (COPD), and disease-modifying factors. Such conditions are known to increase the risk of specific infections (*S. pneumoniae* resistant to penicillin, gram-negative bacilli, *pseudomonas*). The second type is acute in-hospital pneumonia acquired by hospital-admitted patients after 72 h or those that after nosocomial discharge exhibit symptoms within 7 days. The third type occurs in immune-suppressed patients, particularly those with AIDS and those undergoing chemotherapy or other immunosuppressive treatment. In this case, etiological agents could be different of the other two groups.

Diagnosis

In 2019, the American Thorax Society and The National Institute for Health and Care Excellence (NICE) updated the guidelines for the management of CAP, including the assessment of severity and mortality risk. Scores like pneumonia severity index (PSI), CURB65, and SMART-COP have been described to determine the severity of CAP (Metlay et al., 2019; National Institute of Health and Care Excellence (NICE), 2014; Metlay et al., 1997). The most frequently present symptoms of CAP are fever (80%), polypnea (45–70%), chest pain (30%), cough, dyspnoea, expectoration, fever, gastrointestinal symptoms, tachycardia, and pleuropulmonary findings. Given the acute nature of these symptoms, patients usually seek medical help within the first 5 days of the onset of symptoms (Metlay et al., 2019; National Institute of Health and Care Excellence (NICE), 2014).

PSI score assign 5 types of risk classes (Fine et al., 1997). Patients with less than 50 years of age and without any of the health coexisting conditions and abnormalities on physical examination showed in Table 1 are assigned to risk class I. The other risk classes are assigned according Tables 1 and 2. The risk of mortality and the treatment recommendations are shown in Table 2.

Another useful severity index is the CURB 65 score (Lim et al., 2003). This score assigns 1 point for each adverse characteristic showed in Table 3. The risk of mortality and the treatment recommendations are shown in Table 4.

Table 1 PSI score calculation.

Age		Health coexisting conditions		Health status	
Age men	Age (years)	Nursing home resident	+10	Altered mental status (disorientation)	+20
Age women	Age (years)—10	Neoplastic disease	+30	Respiratory rate >30/min	+20
		Liver disease	+20	Systolic blood pressure <90 mmHg	+20
		Congestive heart failure	+10	Temperature <35 °C or >40 °C	+15
		Cerebrovascular disease	+10	Pulse >125/min	+10
		Renal disease	+10	Arterial pH <7.35	+30
				Blood urea nitrogen >30 mg/dL (11 mmol/L)	+20
				Sodium <130 mmol/l	+20
				Glucose >250 mg/dL (14 mmol/L)	+10
				Hematocrit <30%	+10
			Partial pressure of arterial oxygen <60 mmHg	+10	
Total age score		Total health coexisting conditions		Total health status	
Total score = Total age score + Total health coexisting condition + Total health status					

Data were obtained from Fine MJ, Auble TE, Yealy DM, Hanusa BH, Weissfeld LA, Singer DE, Coley CM, Marrie TJ, and Kapoor WN (1997) A prediction rule to identify low-risk patients with community-acquired pneumonia. *New England Journal of Medicine*. <https://doi.org/10.1056/NEJM199701233360402>.

Table 2 Risk class assignment according to PSI score.

Risk class	Score	Risk of mortality %	Recommendations
I		0.1	Outpatient treatment or an abbreviated course of inpatient care
II	<70	0.6	
III	71–90	2.8	
IV	91–130	8.2	Inpatient care
V	>130	29.2	

Data were obtained from Fine MJ, Auble TE, Yealy DM, Hanusa BH, Weissfeld LA, Singer DE, Coley CM, Marrie TJ, and Kapoor WN (1997) A prediction rule to identify low-risk patients with community-acquired pneumonia. *New England Journal of Medicine*. <https://doi.org/10.1056/NEJM199701233360402>.

Table 3 CURB 65 score adverse features.

C	Confusion
U	Urea >7 mmol/L
R	Respiratory rate >30/min
B	Low blood pressure (systolic <90 mmHg or diastolic <60 mmHg)
65	Age >65

Data were obtained from Lim WS, van der Eerden MM, Laing R, Boersma WG, Karalus N, Town GI, Lewis SA, and Macfarlane JT (2003) Defining community acquired pneumonia severity on presentation to hospital: An international derivation and validation study. *Thorax* 58: 377–382.

Table 4 CURB 65 score.

Number of adverse prognostic features	Group assigned	Risk of mortality %	Recommendations
0	1	Low 1.5	Likely suitable for home treatment
1			
2	2	Intermediate 9.2	Consider hospital supervised treatment
3	3	High 22	Manage in hospital as severe pneumonia
4			
5			

Data were obtained from Lim WS, van der Eerden MM, Laing R, Boersma WG, Karalus N, Town GI, Lewis SA, and Macfarlane JT (2003) Defining community acquired pneumonia severity on presentation to hospital: An international derivation and validation study. *Thorax* 58: 377–382.

In clinical research studies, the presence of new pulmonary infiltrates in the radiological chest pair (RxTx) is used as a gold standard for the diagnosis of CAP, together with the presence of already analyzed suggestive signs and symptoms. Although the sensitivity and specificity of RxTx varies from 30% to 70%, current guidelines indicate that it has a good performance in patients with suspected pneumonia (Mandell et al., 2007; Torres and Rodriguez de Castro, 2020).

Etiology

The distribution and frequency of agents responsible for CAP are very diverse and depend on where the study is conducted and the diagnostic methodology used. Despite this, most studies have identified *S. pneumoniae* as the main cause of CAP, often followed by *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Legionella pneumophila*, *Chlamydia pneumoniae*, *Moraxella catarrhalis*, and influenza virus A. More than 90% of CAPs are produced by these agents. Respiratory viruses are the most important etiological agents during the first years of life (Cilloniz et al., 2016). *Mycoplasma pneumoniae* has the predominant etiological role in the pneumonia developed in school-age children and adolescents. *H. influenzae* type b has also been responsible for bacterial pneumonia in children. The incidence of this microorganism has decreased since the inclusion of the vaccine against it in childhood vaccination schedules (Cilloniz et al., 2016). *Staphylococcus aureus* is responsible for between 2% and 5% of cases, with particular significance among the elderly, where it can become a rare complication of the flu. The incidence of community methicillin-resistant *Staphylococcus aureus* continues to remain low but still represents a serious problem owing to its aggressive pathogenesis. More specifically, the presence of the Panton-Valentine leukocidin carrier causes serious necrotizing pneumonia even in healthy people without underlying diseases. Gram-negative bacilli are responsible for 5–10% of cases and are particularly important agents among residents of nursing homes and alcoholics (Cilloniz et al., 2016).

Pathogenesis

In absence of disease, pulmonary defense mechanisms maintain sterile infraglottic airways, except in smokers and chronic bronchitis patients, whose infraglottic airway is usually colonized by oropharyngeal flora. Through micro aspirations or aerosolized material, such as that produced by a sneeze, microorganisms enter the pulmonary parenchyma following the canalicular pathway. The presence of ciliated cylindrical epithelium and mucus-producing cells along the airway forms a defensive barrier that microorganisms must overcome to reach the pulmonary parenchyma. Other defense mechanisms are the saliva level, pH, local production of complement and secretory IgA, and macrophages that act as phagocytic cells.

Microorganisms have adhesion mechanisms such as hemagglutinins in influenza viruses and pili, exotoxins, and proteolytic enzymes in bacteria. When the pathogens overcome these anatomical, mechanical, and physiological barriers, they are then able to reach the lung tissue, and activate immune cells producing inflammatory response mediators that attract neutrophils to the site of infection. The presence of specific IgGs stimulates the activation of the classical complement pathway, fundamental in the antibacterial response. Cell-mediated immunity plays a fundamental role in intracellular infections (viruses, mycoplasmas, chlamydias, *Legionella*, and *Mycobacterium*) (Blanquer et al., 2011).

There are some factors that can interfere with defense mechanisms and must be considered to understand the pathogenesis of this infection. For example, changes in the level of wakefulness (alcoholic intoxication, central nervous system depressant drugs, stroke, etc.) may compromise epiglottic closure and produce aspiration of the content of the oropharynx. Furthermore, cigarette smoke can also disrupt mucociliary function and macrophage activity. The high viral load respiratory infections destroy the respiratory epithelium and alter the chemotaxis of neutrophils. Alcoholism, in addition to wakefulness disorders, decrease cough reflexes, which in turn predisposes the person to colonization by gram-negative bacilli, by decreasing neutrophil mobilization and secretion of IgA. Manipulations of the digestive and respiratory tract also alter the mechanisms of defense, e.g. orotracheal intubation, nasogastric tube placement, and fibroscopy. Others factors that alter local defense mechanisms are alveolar edema in CHF, hypoxemia, acidosis, malnutrition, uraemia, age (due to immaturity of the immune system in infants or old age in those over 65), alterations in the production of immunoglobulins (chronic myeloid leukemia, multiple myeloma, nephrotic syndrome, etc.), underlying respiratory system disorders (COPD, bronchiectasis, cystic fibrosis), and extrinsic compressions (adenopathies, bronchopulmonary tumors). In some cases, it is not possible to identify any of the above-mentioned predisposing factors, but it is important to keep in mind the role of virulence factors of different microorganisms in the host attack, highlighting in particular *S. pneumoniae* (Metlay et al., 2019).

Clinical manifestations

Classically, from a clinical point of view, there has been a differentiation between typical or usual bacterial and atypical pneumonia. Although currently the overall specificity of the signs and symptoms of the determined etiology have been put into doubt, it is still considered useful to maintain the mentioned subgroups for educational purposes. Typical pneumonia is usually caused by *S. pneumoniae*, *H. influenzae*, and gram-negative bacilli such as *S. aureus* (Torres and Rodriguez de Castro, 2020). The disease is characterized by its abrupt beginning, although it may be preceded by a catarrhal syndrome. Cold sores, a high fever (absent in the elderly) and an initial dry cough, which is then productive with mucopurulent, or rusty expectoration are also possible symptoms.

Such symptoms can be accompanied by side stitch pain and nasal flutter. During the clinical examination, patients present with a toxic appearance, polypnea, fever, sweatiness, and with signs of parenchymal condensation (decreased vibrations, dullness, crackling rales). Chest radiology shows homogeneous opacity with air bronchogram affecting one or several lung segments, being able to occupy an entire lobe.

Atypical pneumonia is produced by microorganisms such as *M. pneumoniae* or *C. pneumoniae*. It is characterized by an insidious onset with headache, asthenia, malaise, persistent dry cough with poor or no expectoration, fever, and thoracic pain that increases with a cough. Extra-respiratory symptoms such as nausea, vomiting, skin rash, arthromyalgia, rhinorrhea, dysphonia, and odynophagia are also frequent. Pulmonary auscultation reveals the presence of fine crackles, although this may be normal. An interstitial pattern with opacity of the reticulonodular type is observed on the radiograph. The lower lobes are the most frequently affected.

Pneumonia among the elderly is also of particular interest as it is three to five times more frequent and leads to a higher mortality (close to 30%). Indeed, it is the first cause of infectious mortality in this age group. The most frequently involved agents are *S. pneumoniae*, *H. influenzae*, *K. pneumoniae*, *S. aureus*, and *influenza virus A* and *B*. In recent years, the respiratory syncytial virus (RSV) was recognized as an agent of increasing importance in this age group. The clinical presentation of pneumonia among the elderly shows a high degree of unspecific symptoms. In some cases, unexplained tachycardia and disorders in the level of wakefulness without fever may also be present. In terms of radiology, a dimmer opacity makes the diagnosis difficult. Further, healing and radiological resolutions are slower among elderly patients, and the prognosis depends on the delay in the initiation of the treatment, the etiology and the presence of comorbidities.

Etiological diagnosis

Microbiological studies allow us to identify the causative agent of pneumonia and to determine its sensitivity and resistance to antimicrobials. Identifying the responsible microorganism allows us to provide a targeted treatment with greater therapeutic possibilities, thus reducing the antimicrobial spectrum, antibiotic resistance and costs. However, microbiological studies are not recommended for all patients with CAP. The most commonly performed tests are the cultivation of respiratory secretions, either obtained by spontaneous expectoration or through endoscopic, blood culture, serological tests and molecular biology diagnostic tests. The culture of tracheobronchial secretions can be done through non-invasive (sputum) or invasive (bronchio-alveolar lavage) methods. Laboratory processing and clinical interpretation of the results differs for each type of sample (Blanquer et al., 2011; Miller et al., 2018).

Sputum culture

Sputum culture has variable sensitivity and specificity and does not contribute significantly to the initial management of the patient. This method has limitations that condition its performance, such as the inability to obtain adequate samples in more than one-third of the patients and reduction in its sensitivity with the previous use of antibiotics. Samples must be representative of the lower respiratory tract and meet Murray's criteria: more than 25 polymorphonuclear and less than 10 epithelial cells (Blanquer et al., 2011; Miller et al., 2018).

All patients with moderate to severe CAP will be requested to be able to expectorate. In patients with severe CAP or therapeutic failure, it is recommended to extract the culture of sputum or another sample from the lower respiratory tract. Samples should arrive at the laboratory less than 2 h after extraction or stored in a refrigerator at -4°C for up to 24 h. If these measures cannot be secured, the study should not be conducted. The samples obtained by endoscopy are more representative of the parenchymal focus as they overcome the possible oropharyngeal contamination. It is a non-morbidity-free invasive method that should not be applied routinely. Thus, its performance is justified in a certain group of patients, such as immunocompromised patients, those admitted to the intensive care unit (ICU), and those with torpid evolution, among others. The universally used sample is, however, bronchio-alveolar lavage (BAL).

Blood culture

Blood cultures in general, do not modify the beginning of the empirical therapy and will be requested in cases such as severe CAP, presence of pleural effusion or cavity, leukopenia, alcoholism, chronic liver disease, anatomical or functional asplenia, or pneumococcal antigen in urine (Mandell et al., 2007; Woodhead et al., 2011). Blood culture should be preferably performed prior to the start of antimicrobial treatment. Although the objective of blood cultures is to achieve a microbiological diagnosis, they are positive in 7–16% of cases and have a high rate of false positives. *S. pneumoniae* is the most frequent microorganism found in blood cultures. Aerobic culture in blood agar with CO_2 atmosphere allows recovery of aerobic bacteria such as *S. pneumoniae*, *H. influenzae*, *Moraxella catarrhalis*, *S. aureus*, *K. pneumoniae* and *P. aeruginosa*. If Gram staining does not show a predominance of a bacterial type, but an abundant number of inflammatory cells is observed, the presence of fastidious bacteria or viral agents must be suspected. Some microbiology laboratories have designed expanded culture protocols when this situation occurs which includes viral cultures. Antimicrobial susceptibility studies are carried out on the bacterial species identified in the culture.

Urinary antigens

The urinary antigen test for *S. pneumoniae* is a simple, accessible, and well-established test in current clinical practice. It has a sensitivity of 74% and specificity of 97.2% (Lacoma et al., 2012; Sinclair et al., 2013). The test may remain positive after beginning antibiotic treatment, so it is not recommended for patients who have suffered from CAP in the month prior to the test. All patients with moderate-severe CAP will be requested to do such a test. Urinary antigen for *Legionella pneumophila* is useful to identify *Legionella pneumophila* group 1, which is responsible for 80% of legionellosis pneumonia. The test has a sensitivity of 70–90% and specificity close to 99% (Lacoma et al., 2012). The antigen is positive from day 1 of the disease, which continues for weeks. The test is recommended for the following situations: (1) very severe CAP entering the ICU, (2) CAP that does not respond to treatment with β -lactams, (3) patients with risk factors e.g. trip to endemic areas in the 10 days prior, (4) notion of use of heating or air conditioning, (5) certain occupations such as plumbing system repair, and (6) immunocompromised patients. The etiological diagnosis is validated using the PCR method. In some hospitals there is a multiple PCR team for etiological diagnosis. This test is available for patients with severe CAP who require admission to the ICU and for immune-compromised patients (Herrera et al., 2016).

In addition, there are serological tests to detect serum antibodies (IgG and IgM) against *M. pneumoniae*, *L. pneumophila*, *C. pneumoniae* and *C. psittaci*, being especially useful in the latter due its high sensitivity and specificity. In general, it is necessary to obtain two samples in the acute phase and in the convalescence phase, with an interval of 4–6 weeks, to determine seroconversion (Almirall et al., 2004; Herrera et al., 2016). These samples will be obtained from patients entering the ICU and patients with epidemiological suspicion. In addition, in cases of pleural effusion, a study of pleural fluid will be requested and a diagnostic thoracentesis will always be performed except when there are contraindications with Gram staining culture and pneumococcal antigen (Woodhead et al., 2011).

Treatment

Antimicrobial treatment (AT) in CAP is essential for its adequate resolution. Its early indication reduces complications, recovery times, morbidity and mortality (Mandell et al., 2007; Metlay et al., 2019; National Institute of Health and Care Excellence (NICE), 2014). There are currently multiple international guides, which have been a reference in the selection of treatment. One of them is the IDSA guides of the British Thoracic Society, SEPAR. However, the trend in current clinical practice is to achieve a therapeutic consensus that reflects local reality and available resources. The empirical AT selected must meet certain conditions such as to have demonstrated activity against the most frequent microorganisms that cause CAP, to have considered the patient's risk factors and comorbidities, and to have been evaluated over time, thus allowing changes related to the epidemiological evolution itself. The onset of antibiotic treatment cannot be conditioned to the isolation of the microorganism. The published series shows that the etiologic agents are usually the same, and the antibiotic sensitivity pattern must be hierarchized. This particularity makes the treatment of CAP fundamentally empirical. Therefore, there is currently no reason to defer the initiation of AT, which should be started as soon as possible. The active plan will always include an active antibiotic against *Streptococcus pneumoniae*, which is the most common etiological microorganism. The most used antibiotics are β -lactams, which are bactericides antibiotics. The risk factors that suggest a decreased sensitivity of *S. pneumoniae* are: age 65 or older, immunosuppression, having received β -lactams in the last 3 months, living in nursing home, poor socio-economic environment, and alcohol abuse. Aminopenicillins (ampicillin and amoxicillin) are equally active against sensitive and intermediately sensitive *S. pneumoniae*. For oral administration, amoxicillin is preferred as it is better absorbed. Many strains of *Staphylococcus* spp., *H. influenzae*, *K. pneumoniae*, *E. coli*, and *M. catarrhalis* (β lactamase producers) are currently resistant to aminopenicillins, so empirical use is not recommended when it is suspected that the infection is caused by these organisms. β lactamase inhibitors (clavulanic acid or sulbactam) recover aminopenicillin activity against most cited strains. Third-generation cephalosporins are the most active cephalosporins against gram-negative bacilli. Ceftriaxone and cefotaxime are the most active against gram-positive, with the exception of *Enterococcus* spp. and *Listeria monocytogenes*. Ceftazidime has antipseudomonal activity but is not very active against *S. aureus* and other microbes. Macrolides (erythromycin, clarithromycin, azithromycin), are indicated when there is suspicion of CAP for "atypical germs," because they do not reach sufficient serum concentrations. Macrolides should not be used if there is suspicion of bacteraemia, nor in patients with moderately severe or severe illness.

Tuberculosis

Tuberculosis (TB) is a re-emerging disease and also one of the most important infectious diseases worldwide. It is caused by the bacterium *Mycobacterium tuberculosis* which remains one of the most difficult pathogens to control. The annual World Health Organization (WHO) report shows that, despite advances in disease control, tuberculosis is still causing a large disease burden worldwide (Kyu et al., 2018).

In 2015, more than 10 million new or relapsed TB cases and more than a million TB-related deaths were reported. It has been estimated that a third of the global population carries a latent TB infection and that approximately 10% of these infections will reactivate and progress to infectious clinical TB in the person's lifetime, thus maintaining transmission in humans. Further, at least a third of human immunodeficiency virus (HIV)-related deaths is attributed to TB. Thus, efforts to prevent TB are advisable in countries with high rates of the disease (Kyu et al., 2018).

Physiopathology

TB transmission occurs via inhalation of droplets expelled by an individual with pulmonary or laryngeal TB coughs, sneezes, or speaks. Droplet nuclei can remain suspended in the air for hours. Moreover, only a subset of the bacteria-laden aerosol droplets of 5 µm diameter with 1–3 bacilli that are inhaled actually reach any alveolar sac. This is because larger size droplets (>5 µm) are trapped in the upper respiratory system by mucus and ciliary action. After being inhaled, bacteria are phagocytosed by alveolar macrophages. Transmission rarely occurs through direct contact with fomites. The risk of transmission is directly correlated with the closeness of contact and amount of time spent with a contagious case (Highsmith et al., 2019). In some cases, macrophages are unable to destroy the bacteria, which then grow inside the phagosome of infected macrophages. After that, a granuloma is generated in the focus of infection. In many cases, activation of the infected macrophages leads to destruction of the bacteria, which allows growth control. However, the presence of latent bacteria inside necrotic tissue can also lead to a latent infection. Some bacteria are then drained into the alveolar space, where they can reactivate. This type of latent tuberculosis infection does not generate symptoms and is not infectious. However, in 10% of cases, latent infection can turn into an active tuberculosis disease. Progress from tuberculosis infection to tuberculosis disease can occur early (primary form) or a period of time after infection (reactivation). The risk of reactivation increases with alterations of the immune system, such as immune deficiencies caused, for example, by HIV; drugs affecting the immune system and other pathologies. In primary or reactivation disease, the lungs are the most commonly affected organ. Nevertheless, the infection can sometimes spread during the primary phase of the infection and reach distant organ systems (Weinberger et al., 2019).

Clinical manifestations

The clinical manifestations of latent and active TB infection show important differences. Latent infection does not show any clinically apparent disease and the only mark of infection is a positive reaction to a skin tuberculin test for delayed hypersensitivity. Patients with latent infection are not contagious. Meanwhile, patients with active disease can show relatively nonspecific symptoms such as weight loss, anorexia, fatigue, low-grade fever, cough, and chest pain occasionally. Patients with disseminated tuberculosis can also show symptoms which result from a particular organ being affected. The most common regions affected by disseminated tuberculosis are: pleura, peritoneum, kidney, adrenal glands, bones, and central nervous system (Weinberger et al., 2019).

Diagnosis

The most commonly used diagnostic method for TB is the tuberculin skin test. This test shows whether the patient has been exposed to *M. tuberculosis*, independently of whether the disease is active, latent, or whether the patient has had a previous infection. For this test, a small amount of protein from bacteria is intradermally injected into the forearm. Individuals who have been infected with *M. tuberculosis* exhibit swelling at the site of injection after 48–72 h. The tuberculin skin test is easy to perform but has an important number of false negative and false positive results (Weinberger et al., 2019). For the diagnosis of active tuberculosis, the initial diagnostic tool is a chest radiograph. In the primary disease, the chest radiograph shows a nonspecific infiltrate and sometimes lymph node enlargement. After the primary disease heals, a radiograph can reveal small calcified lesions due to the collection of calcified granulomas.

A rigorous diagnosis of tuberculosis is done by culturing bacteria from either secretions or tissue. However, *M. tuberculosis* is a slow-growing bacterium, and approximately 6 weeks are required for sufficient growth time, identification and the establishment of antibiotic sensitivity. A more useful and faster diagnosis procedure is through staining of material obtained from the tracheobronchial tree (sputum, tracheobronchial washing or biopsy). Mycobacteria are characterized by the fact that they retain certain dyes, even after exposure to acid. The Ziehl-Neelsen, Kinyoun, or an auramine-rhodamine fluorescent stain can easily detect the presence of an acid-fast bacillus that is clinically significant in the majority of cases. Besides this, nucleic acid amplification assays (PCR) which can detect *M. tuberculosis* in respiratory specimens with good sensitivity and specificity have also been developed (Weinberger et al., 2019).

Treatment and prevention

Most cases of TB are curable with appropriate drug therapy. Patients must be treated with at least two drugs for a long period of time which is generally of 6 months. One of the most common therapy plans for TB includes isoniazid and rifampin for 6 months plus pyrazinamide for the first 2 months. Moreover, due to the presence of resistant strains, ethambutol is added at the initiation of therapy until the acquirement of the drug-resistant profile. When resistance to agents is documented by inhibitory assays, it is possible to elaborate a specific regimen and duration of therapy. Patient's whose sputum has become smear-negative on three successive samples are considered to no longer be infectious, which demonstrates a successful clinical response to therapy (Weinberger et al., 2019).

Due to the long treatment period, an important issue in TB therapy is the patient's adherence. An incomplete or intermittent therapy can lead to treatment failure and the emergence of resistant organisms. Further, due to hepatotoxicity problems which can arise as a result of the medication, patients should be monitored during therapy. Another important challenge in this field is the association between tuberculosis and HIV/AIDS. The drugs used for these diseases can interact, leading to an increase in the

probability of hepatotoxicity and other adverse reactions. In the case of patients with latent tuberculosis, treatment consists in the administration of isoniazid for 9 months, although other regimens are also used. The treatment of patients with latent tuberculosis decreases the probability of the activation of the infection (Weinberger et al., 2019).

The current vaccine for TB, *Mycobacterium bovis* bacilli Calmette-Guerin (BCG), is extensively used as part of the Expanded Program on Immunization. The vaccine has mitigated severe disseminated forms of tuberculosis in children, but shows mixed effectivity results in other age groups. Because BCG does not provide adequate protection against pulmonary disease, new vaccine candidates are being developed to control the disease. The goal of the vaccine candidates is to induce robust immune responses critical for controlling progression of *Mycobacterium tuberculosis* infection. Currently, there are 13 vaccines in clinical development, which can be divided into whole cell-derived vaccines or viral vectored subunit vaccines and adjuvanted protein subunit vaccines (Kaufmann et al., 2014). Recently, investigators reported some approaches to improve the efficacy and protection of BCG, such as development of recombinant subunit vaccines. Other options include an engineering BCG by inserting genes for *Mycobacterium tuberculosis* antigens as well as cytokines and bacterial toxin-derived adjuvants (Nieuwenhuizen and Kaufmann, 2018).

Global impact of respiratory virus diseases

The reemergence of H1N1 in 2009 and the outbreak of SARS-CoV-2, a novel pandemic virus in 2019, have alerted the world to the fact that a virus can emerge and spread globally in a matter of days. Thousands of deaths and huge economic losses are the main consequences of a pandemic. The large reservoir of viruses that animals have and their potential to infect humans imply that the emergence of new respiratory pathogens is guaranteed. Furthermore, the efficient human-to-human transmission of respiratory viruses makes controlling them challenging (WHO, 2018). The respiratory viral infections are the most frequent reason for seeking medical care, which is reflected in the substantial number of hospital and emergency room visits by people from all ages groups (GBD 2017 DALYs and HALE Collaborators, 2018).

In general, respiratory viruses are transmitted directly by contact with infected respiratory droplets or by contact with contaminated fomites. The survival and infective capacity of viruses on surfaces, which can range from a few hours to days, depend on several factors such as porosity of the surfaces and the characteristics of the virus. Nonenveloped viruses are more stable in the environment than enveloped viruses and can probably cause infection through direct contact (Boone and Gerba, 2007).

Clinical outcomes

Respiratory viruses affect the upper respiratory tract and are responsible for diseases such as rhinosinusitis or the “common cold,” otitis media, sinusitis and laryngitis. Such viruses can also affect deeper structures below the larynx, causing bronchiolitis, bronchitis, acute pneumonia, exacerbation of asthma and chronic lung disorders (WHO, 2012, 2018a). Respiratory viruses increase the risk of secondary bacterial infections and also are known to have been associated in half of the pneumonia cases. They are also the main cause of cases of bronchiolitis and asthma exacerbations in infants. In adults, respiratory virus is majority implicated in asthma exacerbations, and COPD exacerbations (WHO, 2012). Although specific pathogens commonly cause characteristic clinical manifestations, there are significant similarities in the clinical symptoms associated with the different viruses causing respiratory illnesses (Table 1).

Influenza virus (IV)

Influenza viruses are the leading cause of seasonal flu epidemics that occur almost every winter and 5% to 10% of the human population. IV infection can lead to severe morbidity. It has a higher mortality rate among elderly patients, small children, and individuals with chronic respiratory disease or immune compromised condition (WHO, 2018b).

Influenza viruses belong to the Orthomyxoviridae family. They are enveloped negative-sense single-stranded segmented RNA viruses. The family comprises five genera, but only influenza A and B, which can cause seasonal and occasionally epidemic flu, are of medical importance in humans. Influenza A (IAV) are the only influenza viruses known to have pandemic potential (WHO, 2018b). There are different subtypes of IAV, based on the antigenic properties of hemagglutinin (HA) and neuraminidase (NA) that are two major viral antigens glycoproteins on the surface of the virus. In turn, there are 18 different hemagglutinin subtypes and 11 different neuraminidase subtypes (H1 through H18 and N1 through N11, respectively). Influenza A virion may display any combination of the two proteins on the surface (Centers for Disease Control and Prevention, 2017). A specific characteristic of IAV is

Table 1 Diseases and disorders commonly associated with respiratory viral pathogens.

that they spread in domestic animals, pigs, horses, poultry, and wild migratory birds. These animals are a source of antigenically diverse HA and NA genes that can be exchanged between viral strains by reassortment after co-infection of the same host, causing the generation of human pandemic influenza virus strains with HA and/or NA derived from animal strains. Pandemic influenza arises every 10–50 years and is the result of the emergence of a new IAV virus strain that is antigenically very different from circulating strains already known. Indeed, the lack of preexisting immunity in humans is often correlated with the severity of the infection and high mortality (Krammer et al., 2018). In 2009, the WHO declared an influenza pandemic caused by a new H1N1 strain (pdm09H1N1). The outbreak of the pandemic started in Mexico and the infected subjects presented severe pneumonitis which leads to a high case-mortality rate. Afterward, the disease rapidly disseminated to 72 other countries leading to hundreds of thousands of infected subjects and numerous hundred deceased (Centers for Disease Control and Prevention, 2009).

Clinical manifestations

Transmission of influenza in humans occurs through direct contact with infected subjects, or inhalation of small respiratory droplets from infected subjects (WHO, 2018b). NA plays a role in facilitating viral entry into epithelial cells lying underneath the mucus in the nasopharynx by cleaving the sialic acids from the mucus glycoproteins to free the mucus trapped-virus. HA attachment to the receptor allows cellular entry of the virus (Taubenberger and Morens, 2008). Signs and symptoms of uncomplicated influenza frequently overlap with those of other respiratory viral infections. Initial clinical signs include chills, fever, myalgia, fatigue and headache. The onset of these symptoms can be sudden, especially a high fever. Symptoms such as dry cough, sore or dry throat (possibly with hoarseness) and nasal obstruction can help in the differentiation from other respiratory viral infection. Elderly people and immune suppressed individuals may not develop a fever. Presentation in children can include diarrhea and in adults vomiting may also occur. Flu symptoms tend to last for 2 weeks, and not all flu patients display all of the clinical manifestations. People at greater risk of severe disease or complications include pregnant women, children under 59 months, elderly people, individuals with immunosuppressive conditions or with chronic medical conditions, such as allergic asthma and chronic lung disease. Complications include secondary pneumonia caused by bacteria such as *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus pneumoniae* (Krammer et al., 2018; Uyeki, 2017; van der Sluijs et al., 2010; WHO, 2018b).

Antivirals and vaccines

The treatment of flu includes blockers of polymeric M2-mediated ion-channel activity and neuraminidase inhibitors (NAIs), both drugs are approved by the FDA, but the first one is globally no longer recommended for clinical use due to the widespread resistance among the circulating IAV. NAIs inhibit the release of virus progeny from infected cells and thus reduce viral spread. NAIs include Oseltamivir (commercially named Tamiflu), Zanamivir (Relenza), and Laninamivir octanoate (Inavir). All patients with serious or progressive clinical illness associated with suggested or confirmed influenza virus infection should be treated with antiviral drugs at the earliest (Krammer et al., 2018; Takashita et al., 2020; Uyeki, 2017; WHO, 2018b).

The most effective way to prevent IV infection is vaccination. The WHO recommends annual vaccination against influenza for pregnant women, children aged between 6 months to 5 years, elderly people, and individuals with chronic medical conditions and healthcare workers. Vaccination may be less effective in preventing illness among elderly or individuals with chronic conditions, but it reduces severity of disease as well as the incidence of complications and deaths. The composition of seasonal influenza inactivated vaccines may be trivalent, that is consisting of the three most representative types of virus in circulation (two subtypes of influenza A viruses and one influenza B virus) or quadrivalent, to provide wider protection against influenza B virus infections. Virus strains included in vaccines need to be changed annually due to constantly antigenic drift of the circulating viruses. The WHO Global Influenza Surveillance and Response System continuously monitor the influenza viruses circulating in humans and updates the viruses that match both antigenically and genetically with the causative viruses of the particular flu season (northern and southern hemisphere) for influenza vaccine inclusion (WHO, 2018b).

Coronavirus (CoV)

Until the outbreak of the severe acute respiratory syndrome (SARS) in 2002 (Ksiazek et al., 2003), corona viruses were known as an ordinary cause of the common cold and were not considered to be highly pathogenic in humans. SARS alerted the WHO of the emergence of new corona viruses, which was later confirmed by the Middle East respiratory syndrome (MERS) outbreak in 2012 (WHO, 2019) and the recent coronavirus disease (COVID-19) pandemic caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). SARS-CoV-2 was first recognized in Wuhan, China, in December 2019 and rapidly spread worldwide. Globally, at the date of this publication, 120.383.919 COVID-19 cases had been confirmed, including 2.664.386 deaths reported to WHO (WHO, 2021a).

Coronaviridae is a large family of enveloped positive-sense single-stranded RNA viruses, classified into different genera as alpha, beta, gamma, and delta virus. Their tendency for recombination and the inherently high mutation rates allow these RNA viruses to adapt to multiple species, and crossover from animals to humans, which leads to outbreaks. Alpha and Beta coronaviruses only infect mammals, causing respiratory disorders in humans and gastroenteritis in animals. Gamma and Delta coronaviruses infect birds, but can also infect mammals (Woo et al., 2012). All seven human coronaviruses are known to have animal origins.

The novel coronavirus SARS-CoV-2, is a beta coronavirus that is structurally and functionally related to two bat-derived SARS-like coronaviruses, and to the epidemic SARS-CoV (79% similarity) and MERS-CoV (50% similarity) (Lu et al., 2020). Coronaviruses entry into the host cells is mediated by the external glycoprotein spike S. The protein consists of two functional subunits responsible for binding to the host cell receptor and fusion of the viral and cellular membranes. In SARS-CoV-2, angiotensin-converting enzyme 2 (ACE2) has been recently confirmed as the main virus receptor (Hoffmann et al., 2020). ACE2 populates the apical membrane of the respiratory epithelial cells and is also present in the nose and mouth. Like SARS-CoV, SARS-CoV-2 spike recognizes and binds to the ACE2 receptor, primed by the transmembrane protease serine type 2 (TMPRSS2), although affinities remain to be compared (Hoffmann et al., 2020; Walls et al., 2020).

Clinical manifestations and outcomes of SARS-CoV-2

SARS-CoV-2 is transmitted efficiently by human-to-human via droplets or direct contact. It is stable in aerosols for hours and on surfaces up to days (van Doremalen et al., 2020). It has a basal reproductive number of 2.68 that could go up to 4, which is higher than that for SARS-CoV and MERS-CoV. SARS-CoV-2 infection has been estimated to have a mean incubation period of 6.4 days (Wu et al., 2020). The clinical spectrum of SARS-CoV-2 infection can range from no symptoms or mild respiratory symptoms to severe acute respiratory disease and death. People infected with SARS-CoV-2 transmit the virus without recognizing, or prior to recognizing symptoms. This poses a great difficulty for infection control, because these unspecific symptoms are difficult to identify and quarantine. The risk for infection is high for individuals of all ages; however, most COVID-19 patients are middle-aged adults and elderly people. The most frequently found symptoms are fever and cough, but patients can also present with other symptoms such as myalgia, headache, dyspnea, fatigue, chest pain, and nasal congestion. Most patients present with fever together with other symptoms, rather than only fever. Some patients also experience diarrhea, nausea, or vomiting (Wu et al., 2020; Yang et al., 2020). Other manifestations in mild patients are olfactory and gustatory disorders, which appear in patients with no nasal symptoms or before these symptoms appear, these were prevalent symptoms reported outside China (Lechien et al., 2020). The population at the highest risk of developing a severe disease is the elderly and people with certain comorbidities. Severe COVID-19 cases were more likely to have comorbidities than non-severe cases. The most common underlying diseases found in all patients were cardiovascular disease, hypertension, diabetes, chronic respiratory disease, cancer, renal disease, and obesity (Chen et al., 2020; Wang et al., 2020b; Yang et al., 2020). Radiological findings of SARS-CoV-2 pneumonia are variable, with focal unilateral to diffuse bilateral lung involvement with ground-glass opacities being the most typical finding on chest computed tomography (Wang et al., 2020b). The progression of the high-risk disease requires hospitalization, oxygen support, and admission to an intensive care unit (ICU). Moreover, common complications include shock, acute respiratory distress syndrome, arrhythmia, acute cardiac injury, acute kidney injury, secondary infection, and death (Huang et al., 2020; Wang et al., 2020b; Yang et al., 2020).

Clinical management

There is no specific treatment with confirmed efficacy for COVID-19 and clinical management is based on supportive care, such as in other respiratory diseases. Considerations for patients with other severe acute respiratory illness include the early use of empirical antimicrobials and routine corticosteroids but these should be avoided unless they are indicated for asthma exacerbation or chronic obstruction pulmonary disease (WHO, 2021a). Given the lack of a specific antiviral therapy against SARS-CoV-2, several drugs with potential antiviral activities are under active investigation, although the clinical effectiveness of these drugs for the treatment of patients with COVID-19 has not yet been confirmed. Initial reports suggest that the protease inhibitors lopinavir and ritonavir, used to treat infection with HIV, could be potential candidates. However, no benefit was observed with lopinavir-ritonavir treatment in hospitalized adult patients with severe COVID-19. Despite this, treatment combination including these two antivirals and type I interferon seems to be a more promising option (Cao et al., 2020). Another candidate is Remdesivir, an adenosine analogue that has demonstrated activity against RNA viruses in several families, including *Coronaviridae* (such as SARS-CoV and MERS-CoV) (Sheahan et al., 2017) showing recently to be effective in preventing virus replication in in vitro assays (Wang et al., 2020). There are several clinical trials ongoing, some results already available showed that Remdesivir compared to placebo, shortened the recovery

time in adults hospitalized with COVID-19 (Beigel et al., 2020). Hydroxychloroquine is a widely used anti-malarial and autoimmune disease drug, reported to block virus infection interfering with the glycosylation of ACE2 cellular receptors (Wang et al., 2020). Although it has been tested in clinical studies, they have not obtained conclusive results and its use is not even recommended for the treatment of COVID-19 (US NIH, 2020). Inhibition or modulation of the receptor ACE2 or TMPRSS2 is one of the proposed host-based strategies for the treatment of SARS-CoV-2. The soluble recombinant human ACE2 could inhibit the attachment of the virus to the cells (Monteil et al., 2020). Furthermore, a clinically proven TMPRSS2 inhibitor has also been proposed as a potential treatment option (Hoffmann et al., 2020). Other therapeutic targets involve actors of the innate immune system acting by enhancing or attenuating the inflammatory response. Multiple clinical trials on the use of the above-mentioned and other candidates for treatment of COVID-19 are currently underway. Research efforts are also focused on the development of a vaccine, which represents a more long-term strategy for future outbreaks of SARS-CoV-2 (Clinicaltrials.gov, n.d.).

Effective SARS-CoV-2 vaccines are required to control the COVID-19 pandemic. Research efforts were focused around the world to develop and launch effective vaccines against SARS-CoV-2 through advanced molecular biology and biotechnology approaches. Several vaccine platforms are in development, including inactivated viruses, live attenuated viruses, virus-like particles, DNA, RNA, protein subunits, and viral vector vaccines (replicating and non-replicating). To date, the WHO overview summary has included 264 candidate vaccines against COVID-19, of which 82 are under clinical evaluation (WHO, 2021b). Currently there are 3 vaccines that have passed phase IV trials and have been licensed for massive use worldwide: BNT162b2 (Pfizer / BioNTech), mRNA-1273 (Moderna) and AZD1222 (University of Oxford and AstraZeneca) (WHO, 2021b). Vaccination started mainly with these, but in addition at least seven different vaccines have been administered around the world. Vulnerable populations, the elderly and healthcare workers, are the highest priority for vaccination in all countries. Globally a total of 363.691.238 vaccine doses have been administered (WHO, 2021a).

Respiratory syncytial virus (RSV)

RSV is a leading global cause of morbidity and mortality. It is the most common viral pathogen identified in infants and young children with pneumonia or bronchiolitis and the major single cause of hospitalization during infancy. It is also the second most-likely single death-causing pathogen, especially among infants in the first 6 months of life (Nair et al., 2010; Shi et al., 2017). RSV also has been increasingly recognized as a cause of illness in adults, mainly in the elderly and high-risk adults with heart failure or COPD. It has a disease burden comparable to that of the influenza virus in the elderly (Falsey et al., 2005).

RSV is an enveloped non-segmented negative-sense single-stranded RNA virus that belongs to the *Pneumoviridae* family. The envelope of the virus has two glycosylated surface proteins essential for virus infectivity and pathogenesis. The attachment glycoprotein G is responsible for the attachment of the virus to respiratory epithelial cells, while the fusion protein F mediates virion and host cell fusion, thus creating large multinucleated characteristic syncytia by fusing with neighboring cells. Moreover, the F and G proteins stimulate the neutralizing antibody immune response by the host (Collins and Graham, 2008; Vandini et al., 2017). Based on antigenic differences in their glycoproteins G and F, there are two major RSV groups, RSV-A and RSV-B. The differences between the two groups are an extensive antigenic and nucleotide sequence on the G protein. Both groups generally coexist and multiple genotypes within the groups can also co-circulate during an epidemic season. The predominance of one genotype over the others leads to alternating infection incidences each the year and that can be the reason for the ability of RSV to infect previously exposed individuals and circumvent preexisting immune responses (Vandini et al., 2017; Liu et al., 2016; Sullender, 2000).

Clinical manifestations

In children, RSV causes respiratory tract infection from mild upper respiratory tract symptoms to severe lower airway involvement that needs hospital admission and mechanical ventilation. The highest RSV infection occurs in infants that have an increased possibility of lower airway involvement causing bronchiolitis and pneumonia. Host factors like premature delivery, malnutrition, or congenital heart diseases increase the risk of developing an acute disease (Nair et al., 2010). RSV is a highly contagious virus; transmission occurs by inoculation of the nose or eyes, but rarely the mouth, with contaminated secretions or by virus-containing respiratory droplets of an infectious patient (Hall, 2001; Meissner, 2016). The virus can also survive for prolonged periods of time on the skin, clothes, and other objects, thus facilitating its spread (Hall, 2001). The incubation period of RSV is of 2–8 days and after inoculation in the nasopharyngeal epithelium it rapidly spreads to the lower respiratory tract where it infects ciliated epithelial cells. The virus rather infects the bronchioles and type 1 pneumocytes in the alveoli, but can also infect non-ciliated epithelium and intraepithelial dendritic cells (Collins and Graham, 2008; Meissner, 2016). It has been demonstrated that RSV can infect progenitor basal cells and induce morphogenetic changes in the epithelium, resulting in an increased number of goblet cells and reduced number of ciliated cells (Persson et al., 2014). The virus binds to cellular receptors of the target cell using G glycoproteins and the viral attachment begins a conformational change in F protein, promoting fusion of the virus envelope with the host cell membrane to insert its nucleocapsid and begin its intracellular replication (Meissner, 2016). Among the initial clinical manifestations appear upper respiratory tract symptoms like coryza, congestion and rhinorrhea. Also, fever is a predominant symptom in infants. A consequence of the nasal congestion and various symptoms causes of malaise can be poor feeding and subsequent dehydration. Increasing cough is frequently the first sign of lower respiratory tract involvement, followed by the appearance of clinical signs of

bronchiolitis like tachypnea, dyspnea, and the acute phase of the infections is often followed by episodes of increased airway resistance, air trapping, and wheezing. Furthermore, symptoms of lower airway infection are also common in infants with mild disease (Collins and Graham, 2008; Meissner, 2016; Smyth and Openshaw, 2006). Along with the health burden of RSV infection, there is a high possibility of long-term consequences on respiratory function caused by RSV infection, with the development of persistent airway disease (Meissner, 2016; Smyth and Openshaw, 2006). Moreover, adults have less distinctive clinical findings compared to children and the cause is often unclear. Among clinical manifestations are sore throat, fever and malaise as well as lower respiratory tract symptoms such as cough. There is an increased morbidity and mortality in aged patients or patients with underlying immune or cardiorespiratory disease (Falsey et al., 2005; Hall, 2001).

Clinical management

The majority of RSV cases are treated with nonspecific medical intervention. Therapy for acute RSV bronchiolitis in infants is supportive care and includes maintenance of nutrition, hydration and an oxygen saturation of 90%. Antibiotics, bronchodilators or epinephrine are not recommended. Ribavirin is a widely used broad-spectrum antiviral agent. Despite this, it has shown no benefits for RSV bronchiolitis (Smyth and Openshaw, 2006). Developing RSV vaccines has been a challenge, and the difficulty of inducing protective immunity is highlighted by repeat infections throughout life. Currently, there are numerous RSV vaccines in various stages of clinical trials. In the late 1960s a formalin-inactivated RSV vaccine was administered to infants resulting in enhanced RSV disease but with a high rate of hospitalization and two deaths. It was immunogenic but induced poor antibody affinity maturation and antibody avidity for virus epitopes (Kim et al., 1969). The reason for the failure of this vaccine is unclear, but is thought to be, in part, due to formalin-mediated disruption of the neutralizing epitopes (Murphy and Walsh, 1988). It has also been argued that the lack of affinity maturation leads to insufficient TLR activation in B cells (Delgado et al., 2009). An antiviral therapy licensed for RSV prophylaxis, and only available for high-risk infants, is a specific monoclonal antibody called Palivizumab. It is recommended in the first year of life for infants born before 29 weeks, with hemodynamic significant heart disease or chronic lung disease. Palivizumab is not recommended for otherwise healthy infants born at or after 29 weeks, and more information is needed before its use in RSV-primed older children (Simoes et al., 2018). Throughout history, several therapeutic interventions for RSV have failed and still remain a source of scientific interest. RSV molecular epidemiological surveillance of seasonal circulation of different RSV genotypes is essential for identify new viral strains, predict their clinical relevance, and select candidate strains for vaccine and therapeutic development.

Introduction

A common route of fungi infection is via the respiratory tract. The most common fungus diseases of the respiratory system are shown in Table 1. Environmental exposure to spores of pathogenic fungi during occupational or recreational tasks frequently leads to subclinical disease infections or to more severe life-threatening diseases (Queiroz-Telles et al., 2017). Most pulmonary fungal infections only imply temporal colonization of the respiratory tract but sometimes the infection can represent serious infection, leading to different management and prognosis. Generally, in the lung's alveoli, fungus is phagocyted by macrophages and other cells involved in the primary immune response. Some fungi have developed a way to disable the macrophage's neutralization and have acquired the ability to grow and multiply inside macrophages. In these cases, cells from the adaptive immune system can control the infection. In healthy individuals the fungus is contained in most cases, but when cellular immunity is impaired, as for instance, in AIDS patients, infection with an endemic fungus cannot be controlled and could generate a systemic disease.

Aspergillosis

Aspergillus species are a ubiquitous fungus which widely present in the environment. *Aspergillus fumigatus* is the most frequent cause of human infections. Other pathogenic species of *Aspergillus* are *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus terreus*, and *Aspergillus nidulans*.

Table 1 Common fungus diseases.

Disease	Etiological agent
Aspergillosis	<i>Aspergillus fumigatus</i> (most common), <i>Aspergillus flavus</i> , <i>Aspergillus niger</i> , <i>Aspergillus terreus</i> and <i>Aspergillus nidulans</i> .
Histoplasmosis	<i>Histoplasma capsulatum</i>
Coccidioidomycosis	<i>Coccidioides immitis</i> and <i>Coccidioides posadasii</i>
Blastomycosis	<i>Blastomyces dermatitidis</i>
Paracoccidioidomycosis	<i>Paracoccidioides brasiliensis</i>
Cryptococcosis	<i>Cryptococcus neoformans</i> and <i>Cryptococcus gattii</i>
Pneumocystis pneumonia	<i>Pneumocystis jirovecii</i>

The inhalation of the spores (conidia) is a common phenomenon while tissue invasion is infrequent and occurs mainly in patients with some degree of immunosuppression. The mortality of invasive forms depends on the clinical form and the host's immune background but is usually higher than 50%.

Under normal immune function, alveolar macrophages are capable of eliminating the spores inhaled every day. Despite this, the spores that escape macrophage phagocytosis can germinate and become hyphae, in which case they are eliminated by cellular components of the immune system as polymorphonuclear neutrophils. From a clinical point of view, *Aspergillus* species can lead to different types of pathogenesis, from aspergillosis bronchopulmonary allergic (ABPA) and chronic pulmonary forms to invasive and disseminated forms (Fortún et al., 2012; García-Navarro, 2010).

Clinical manifestations

The clinical manifestations depend on the type of infection. ABPA occurs most frequently in patients with chronic asthma or cystic fibrosis and is characterized by episodic airway obstruction and fever. In the case of aspergilloma these cases are characterized by cough, dyspnoea, weight loss, fatigue, chest pain, or fever. Chest radiographs show a ball in a cavity because the fungus matted hyphae and debris are deposited in a preformed cavity from previous pulmonary tuberculosis, histoplasmosis, or fibrocystic sarcoidosis.

Chronic aspergillosis occurs in patients with chronic lung disease or immunosuppressed, commonly due to the use of corticosteroids for a long period of time. Clinical manifestations including cough and dyspnoea could be indistinguishable from the primary chronic respiratory disease. Invasive pulmonary aspergillosis (IPA) occurs in immunocompromised hosts and is characterized by fever, focal pulmonary infiltrates, cough, pleuritic pain, and sometimes hemoptysis (Walsh and Stevens, 2012).

Diagnosis

Due to its nonspecific symptoms which can be confused with chronic pulmonary disease ABPA is an under diagnosed disease. Diagnosis is based on clinical and radiologic aspects and can vary in cases of patients who have other pulmonary diseases such as cystic fibrosis. Diagnosis is based on a positive cutaneous reaction to *A. fumigatus* antigen, immunoglobulin E (IgE) concentration in blood above 1000 IU/mL, presence of *Aspergillus*-specific IgE, peripheral blood eosinophilia, and pulmonary infiltrates.

Aspergillus-specific IgE is the most sensitive screening test for ABPA. If patients with uncontrolled asthma show a positive *Aspergillus*-specific IgE but a total IgE level below 1000 IU/mL and do not meet the additional characteristics, they could be classified as severe asthma with fungal sensitization. The diagnosis of IPA is difficult. Computed tomography could reveal features that can be confused with another type of infection. Microbiologic culture or direct microscopy from bronchoalveolar lavage or biopsy is important to differentiate aspergillosis from other infections. Detection of galactomannan (polysaccharide of *Aspergillus* cell wall) by immunoassay could be also useful (El-Baba et al., 2020; Walsh and Stevens, 2012).

Treatment

There are different treatment alternatives for allergic forms that include glucocorticoids and antifungals. For systemic ABPA the preferred treatment is with glucocorticoids such as prednisolone. The intention of the therapy is to decrease the hypersensitivity response.

Antifungals (itraconazole or voriconazole) could be beneficial in some patients, including those showing a poor response to glucocorticoid monotherapy.

The treatment for invasive forms differs from that for allergic forms because in these cases most patients have immunodeficiencies. Treatment consists of antifungal therapy, a reversal of immune suppression when possible, and in some cases, surgical resection of lesions. The recommended antifungal is voriconazole. In cases where patients have contraindications or a history of hypersensitivity to voriconazole, liposomal amphotericin B is indicated. Second-line therapy may include posaconazole, isavuconazole, or itraconazole.

In the case of immunosuppressed patients, it is important to decrease or suppress corticosteroid treatment and it may also be necessary to establish treatments to accelerate the recovery from neutropenia as the administration of granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor.

Surgical intervention could be necessary in some patients with several forms of invasive aspergillosis, for example those with massive or recurrent hemoptysis or with pulmonary lesions contiguous to important vessels or the pericardium. Furthermore, surgical intervention may be useful in localized disease refractory to antifungal treatment (El-Baba et al., 2020; Walsh and Stevens, 2012).

Histoplasmosis

Histoplasmosis is one of the most common infections by fungi. It is caused by a dimorphic fungus, *Histoplasma capsulatum*. The subspecies *capsulatum* generally causes subclinical infection but high levels of exposure can lead to an asymptomatic pulmonary infection that in immune-compromised patients can lead to a severe infection.

The typical habitat of *H. capsulatum* is soil with high nitrogen content coming from the excrement of birds or bats. Moreover, other risk areas are sites such as chicken coops, bat-infested caves or other places with bird excrement (Fraser et al., 2006; Navarro et al., 2013). Another subspecies of *H. capsulatum*, *duboisii*, is common in Africa and can have different disease manifestations with cutaneous and skeletal affections (Navarro et al., 2013).

H. capsulatum grows as mold below 35 °C while at 37 °C it appears as yeast. The infectious particles are the microconidia spores produced by the mold. After inhalation, spores germinate within bronchioles and alveoli where they grow as yeast-like forms. The alveolar macrophages proceed to control the infection, resulting in localized inflammation. However, in some cases, *H. capsulatum* can survive and reactivate within macrophages. In these cases, complementary immune mechanisms such as specific T-lymphocyte activation, interleukin-12 and interferon γ stimulate activation of macrophages killing the fungus. In immune-compromised patient fungal infection can lead to a disseminated infection and it can be found poorly formed granulomas and a large fungal burden (Christenson and Kleiman, 2018; Navarro et al., 2013).

Clinical manifestations

Clinical manifestations are varied and depend on the inoculum level and health status of the patient. Immunodeficiencies or chronic lung diseases can lead to more severe diseases. Acute pulmonary histoplasmosis infection is generally an asymptomatic or self-limited illness. In the case of showing symptoms, these appear some weeks after exposure and are characterized by fever, fatigue, non-productive cough, and myalgias. Chest radiography shows lobar or multilobe nodular infiltrate.

In the case of patients that were exposed to a high level of spores or in immune-suppressed patients the infection could be severe including high fever, dyspnoea, cough, pericarditis, cyanosis, hemoptysis, and could lead in respiratory failure and disseminated disease.

In contrast, chronic cavitary pulmonary histoplasmosis is a progressive and often fatal respiratory infection of older patients who have chronic obstructive pulmonary disease (COPD). Patient's symptoms include fever, fatigue, anorexia, productive cough, and hemoptysis. Chest radiography shows infiltrates in upper lobe and extensive fibrosis in the lower lobes. Acute disseminated histoplasmosis occurs mostly in immune-suppressed patients. Patients show fever, anorexia, hypotension, dyspnoea, and diffuse lesions in skin, disseminated intravascular coagulation, adult respiratory distress syndrome and acute respiratory failure. This syndrome resembles a sepsis of any bacterial or viral cause.

Finally, chronic progressive disseminated histoplasmosis is another severe form of histoplasmosis. The illness is characterized by fever, ulcerations in the buccal mucosa or nasal vestibule, anorexia, and fatigue. Involvement of most of the organ systems has been detected due to disseminated infection including bowel obstruction or perforation, cerebral granulomas, endocarditis with aortic and mitral valve vegetations, adrenal insufficiency (Kauffman, 2012a; Navarro et al., 2013).

Etiological diagnosis

It is a challenge to obtain a differential diagnosis of symptomatic pulmonary histoplasmosis from tuberculosis and other fungi infections like blastomycosis and coccidioidomycosis when clinical and radiographic findings are similar.

The culture of the *H. capsulatum* is a reliable diagnostic test but unfortunately it involves a long incubation time of 6 weeks. Alternatively, serology diagnosis by complement fixation assays and immunodiffusion tests are available. Another helpful option is an immunoassay that detects *H. capsulatum* polysaccharide antigen in blood and urine. This assay can achieve a sensitivity from 75% to 90% in patients who have acute pulmonary histoplasmosis and disseminated histoplasmosis, but it is not suitable for patients who have chronic cavitary histoplasmosis and mediastinitis histoplasmosis. Moreover, the test can have some cross-reactivity with other fungi infections.

Treatment

The treatment depends on the type of infection and patient health status.

Generally, for mild to moderate infections itraconazole (azoles antimycotic group drug) is the drug of choice, while lipid formulations of amphotericin B are used as initial therapy for severe infections. Acute pulmonary histoplasmosis is usually treated with amphotericin B in severe forms and alternatively with itraconazole in milder infections. Itraconazole is also recommended for chronic cavitary pulmonary histoplasmosis. Immunocompromised patients with severe pulmonary histoplasmosis disease are treated with amphotericin B for 1–2 weeks followed by itraconazole (Kauffman, 2012a; Navarro et al., 2013).

Coccidioidomycosis

Coccidioidomycosis is a pulmonary and systemic disease caused by fungi of the genus *Coccidioides*. Two species are pathogenic, *C. immitis* and *C. posadasii*. Both species caused a similar disease. *Coccidioides* is endemic in semi-arid and arid zones in the Americas exclusively. Endemic zones include the southwestern United States, northern Mexico, and other countries of Central and South America (Guatemala, Honduras, Nicaragua, Colombia, Venezuela, Brazil, Argentina, Bolivia, and Paraguay). Endemic areas are characterized by arid or semi-arid climates, low altitude, alkaline soil, limited rainfall, and mild winters. Mycelia grow in soil during periods of rain, while in dry months arthroconidia develops and aerosolizes, causing the infection. In the United States only, coccidioidomycosis affects 150,000 persons every year.

Patients are infected via inhalation of arthroconidium, leading to fungal proliferation. The first steps of the immune response include the participation of macrophages and neutrophils forming granulomas. Fungi may resist effective phagocytosis in which case infection is controlled by the participation of other cells of the immune system like dendritic cells, and B and T lymphocytes. Disseminated disease is rare and occurs in patients with immunodeficiencies (Anstead et al., 2011; Galgiani, 2012).

Clinical manifestations

Coccidioidomycosis is asymptomatic in more than 60% of patients. These individuals can only be detected by a positive skin test.

Other patients can show the “Valley Fever” (called by San Joaquin Valley of California, an endemic area of coccidioidomycosis) that includes fever, erythema nodosum and multiforme and migratory arthralgias. Most symptomatic patients manifest pulmonary infection symptoms as fever, dry cough, and chest pain. In most patients, acute pulmonary coccidioidomycosis resolves without treatment in a month. However, in some patients, the disease progresses into chronic pulmonary infiltrates and persists for months or years. Aggressive pulmonary coccidioidomycosis occurs more often during pregnancy and in immunosuppressed patients. These patients may also suffer from dissemination outside the lungs. The most common locations are the skin, joints, bones, and meninges. Lesions can range from subacute to chronic but in some patients they may be fatal with detectable fungemia (Anstead et al., 2011; Anstead and Graybill, 2013; Galgiani, 2012).

Etiological diagnosis

Due to the nonspecific symptoms, a history of residence or travel to endemic areas is important information for a suspected diagnosis. Search in tissues, sputum or exudates can be achieved through direct microscopy (spherules with endospores or mycelia) or culture. Because of the high possibility of transmission to lab personnel, culture must be made according to proper biosafety practices. Serological tests are also a useful tool for diagnosing and monitoring the course of infection. The skin test is performed with either coccidioidin (mycelia phase) or spherulin (spherule phase). In the benign forms of coccidioidomycosis, the skin test is positive in almost all of the patients some weeks after the start of infection. However, patients with disseminated disease, have often a negative reaction to the skin test (Anstead et al., 2011; Fraser et al., 2006).

Treatment

Most patients are asymptomatic and most cases of primary pulmonary infection resolve without treatment. However, in detected cases, observation is required for some years until the resolution of the infection to prevent complications.

Antifungal therapy is necessary for patients with severe disease, disseminated disease, or high risk of dissemination. The therapy can include amphotericin B or azole group antifungal (itraconazole, fluconazole, voriconazole) or a combination of both groups (first weeks with amphotericin B and then azole antifungal). Treatment should be prolonged for at least 1 year (Anstead et al., 2011; Galgiani, 2012).

Blastomycosis

Blastomycosis is a pulmonary and sometimes systemic disease caused by *Blastomyces dermatitidis*. Endemic areas include south central and north central regions of the United States and Great lake areas of United States and Canada. Specific zones are those with soil near river basins or lakes. Occasional cases are also reported in Africa, Europe, Asia, and Latin America. Outbreaks are infrequent and are generally related to outdoor activities along waterways. *B. dermatitidis* can infect dogs, cats, and other mammals. Transmission from animals to humans is not possible except, exceptionally, through a dog bite. Infected animals can act as

sentinels to detect sources of outbreaks and to help in the diagnoses. Infection occurs by inhalation of conidia that, upon arrival to the alveoli, transform into yeast and induce an inflammatory response. Alveolar macrophages and neutrophils can inhibit the transition into yeasts. *B. dermatitidis* yeast is relatively resistant and some of them can survive in macrophages. Most infections are asymptomatic and resolve without treatment. Some patients may develop severe pneumonia while others can present with chronic pneumonia.

Infrequently, the infection can disseminate to other sites such as bones and prostate.

Unlike other fungi, blastomycosis has not been reported as an important infection in patients with AIDS. Nevertheless, patients with immunosuppressive conditions have a marked susceptibility (Anstead et al., 2011; Vyas and Bradsher, 2013).

Clinical manifestations

The incubation period of blastomycosis can range from several weeks up to 4 months. Most patients are asymptomatic. Symptomatic patients with acute pneumonia show fever, malaise, and non-productive cough. Skin lesions in the form of painless papules, plaques, nodules, or ulcers along with pneumonia symptoms are suggestive of blastomycosis and other fungus pneumonia. Chest radiography shows pulmonary lobar or multilobar irregular infiltrates, or nodular infiltrates. Patients with chronic pneumonia can show fever, night sweats, fatigue, cough, hemoptysis, and dyspnoea. Chest radiography can show cavitary, nodular or fibrotic lesions. Disseminated disease is characterized by osteomyelitis and skin lesions (Gauthier and Klein, 2018; Kauffman, 2012b).

Etiological diagnosis

Diagnoses can be made by direct examination or culture. A direct examination can be made based on sputum or bronchial washings usually treated with potassium hydroxide.

Culture of *B. dermatitidis* from sputum or bronchial washing gives a definitive diagnosis but results can take up to 4 weeks. Serological tests have low sensitivity and specificity values and have extensive cross-reactivity with other fungal diseases such as histoplasmosis. PCR and antigen test are in development and could be available in the near future (Anstead et al., 2011; Gauthier and Klein, 2018).

Treatment

For severe cases or in immunocompromised patients, amphotericin B or lipid formulation of amphotericin B is recommended for initial therapy. Following improvement of the patient, treatment switches to oral itraconazole. This treatment is prolonged by 6–12 months. In cases of less severe disease, itraconazole is used as initial therapy for 6–12 months (Anstead et al., 2011; Vyas and Bradsher, 2013).

Paracoccidioidomycosis

Paracoccidioidomycosis or South American blastomycosis is an acute or chronic mycosis endemic in humid areas of Central and South America. It is caused by *Paracoccidioides brasiliensis*, a thermally dimorphic fungus. The disease presents in two general forms. The acute form occurs in children and immunocompromised patients and is characterized by dissemination disease. The chronic form affects adults and is mainly characterized by progressive pulmonary lesions.

The fungus can be found in soil and infection occurs when the individual inhales the conidia, resulting in a primary pulmonary lymph node complex. As in other fungus infections, *Paracoccidioides* entry into alveolar macrophages and conidia convert into yeast form. The infection remains localized in the lung but in some cases, systemic dissemination can occur. The infection is predominantly present in males (the male-to-female ratio is 14:1). The reason why adult females are resistant to the disease is that estradiol, inhibits the transformation of the mold into yeast (Kauffman, 2012c; Negroni et al., 2011).

Clinical manifestations

Primary infections are generally asymptomatic, and most individuals will remain free of disease. A positive skin test is the unique evidence of previous infection. Acute or juvenile forms affect pre-puberty children that visited or lived in an endemic area. After a short incubation period, they present with fever, asthenia, anorexia, subcutaneous abscesses, lymphadenopathy, liver and spleen enlargement. Lungs or mucous membrane affection are infrequently. The chronic form usually occurs in adult males that lived in the endemic area and slowly progress over the years. Patients present with asthenia, loss of weight, dyspnoea, and productive cough. Some patients only show pulmonary infection characterized by fever, cough, and dyspnoea. Most patients show multifocal presentation affecting the skin, mucous membranes, lungs, lymph nodes, adrenal glands, abdominal organs, and infrequently, the central nervous system. Typical lesions include oropharyngeal ulcers, lips, and gingival mucosa edema, laryngeal dysphonia, dyspnoea, dysphagia, skin lesions at the face and neck, and hypertrophic cervical lymph nodes. In Brazil, paracoccidioidomycosis is associated with AIDS patients, in which an acute disseminated juvenile type infection is observed (Negroni, 2013; Queiroz-Telles et al., 2017).

Etiological diagnosis

The accurate diagnosis of paracoccidioidomycosis is made through culture, but direct examination could also help to obtain a rapid presumptive result. Direct examination of the samples of bodily fluids and sputum is carried out by treating them with potassium hydroxide and calcofluor fluorescent stain to visualize the fungus. Although culture is the definitive assay, it has the disadvantage that it takes up to 4 weeks to grow. Besides this, immunological assays such as immunodiffusion, ELISA and complement fixation are available to complement the diagnosis (Kauffman, 2012c).

Treatment

Paracoccidioides brasiliensis is sensitive to most antimycotics drugs. The most recommended therapy is treatment with itraconazole or ketoconazole for 6–12 months. Amphotericin B is usually reserved for severe disease. Other treatments include trimethoprim with sulfamethoxazole and sulfadiazine. HIV infected patients are initially treated with amphotericin B followed by trimethoprim-sulfamethoxazole long life suppressive therapy.

Cryptococcosis

Cryptococcosis is a severe infection that mainly affects immunocompromised patients.

The disease is caused by two species of encapsulated yeasts: *Cryptococcus neoformans* and *Cryptococcus gattii*. *C. neoformans* has a worldwide distribution and is an important opportunistic infection in AIDS patients. In contrast, *C. Gattii* is associated with tropical or subtropical regions and usually infects the immune competent host.

Cryptococcus capsular polysaccharide and melanin production are the most important virulence factors. Primary infection occurs via inhalation of yeast into the lung where it is found by macrophages and neutrophils. Moreover, *Cryptococcus* capsules help prevent phagocytosis, so the capsular opsonization is important for appropriate elimination of the yeast. T-cell- mediated immunity also has an important activity against infection by limiting the replication of the yeast. In immunocompetent patients, the infection generally goes asymptomatic and remains localized in the lungs. However, in immune-suppressed patients, yeast can disseminate to other organs, and preferably to neural systems, thus causing meningoencephalitis (Dromer and Lortholary, 2013; Kauffman, 2012d; Thompson and Patterson, 2018).

Clinical manifestations

Many patients with cryptococcal primary pneumonia are asymptomatic, including some immunocompromised patients. In contrast, symptomatic patients can present with fever, chest pain, dyspnoea, and dry cough. AIDS and other immunocompromised patients have a high risk of dissemination that can result in meningoencephalitis and infection of other organs. In this case, patients can suffer from severe headaches, nausea, lethargy, and nuchal rigidity among others signs (Dromer and Lortholary, 2013; Kauffman, 2012d; Thompson and Patterson, 2018).

Etiological diagnosis

The diagnosis could be made through the culture of yeast from sputum, blood, or cerebrospinal fluid, in the case of disseminated disease. *Cryptococcus* suspicious samples are incubated in conventional fungal media for 2 weeks but, in most cases, the organism grows in a few days. Identification can be made based on the capsular staining. Another useful test is a latex agglutination assay that detects cryptococcal polysaccharide antigen. This assay has high sensitivity and specificity in the blood and cerebrospinal fluid of patients with disseminated disease. Sensitivity is reduced in patients with non-disseminated disease. In addition, other commercial immunoassays are also available for detection of cryptococcal antigen, with similar efficacy to the latex assay (Kauffman, 2012d; Thompson and Patterson, 2018).

Treatment

The treatment of pulmonary non-disseminated cryptococcosis depends on the severity of the infection. Most patients have a mild infection and are usually treated with oral fluconazole for 6–12 months. In the case of severe infection or with cryptococcal meningitis, treatment includes an induction phase with amphotericin B and flucytosine for 2 weeks. Then, a consolidation phase with fluconazole for 8–10 weeks. In immunocompromised patients, maintenance treatment with fluconazole could be necessary for a long time. The treatment protocol for *C. gattii* is the same as for *C. neoformans*, albeit some authors prefer voriconazole instead fluconazole for the consolidation phase (Diaz, 2020; Dromer and Lortholary, 2013; Kauffman, 2012d; Thompson and Patterson, 2018).

Pneumocystis jirovecii

Pneumocystis jirovecii, formally called *P. carinii*, is a fungus that causes *Pneumocystis* pneumonia (PCP) in immunocompromised patients. *Pneumocystis jirovecii* has been listed for a long time as a protozoan but currently, based on large molecular genetics studies, is classified as ascomycete fungus. However, information on its life cycle and the route of infection remains unknown.

Serological studies show that pneumocystis has a worldwide distribution and anti-pneumocystis antibodies are found in most people at an early age. Pneumocystis seems to be transmitted by respiratory route between human hosts and there is no evidence of transmission from animals, water, soil, or fomites. Despite the fact that serological studies indicate that pneumocystis infection is widespread, immunocompetent hosts do not show any symptoms or signs of significant disease (Kovacs, 2012).

Clinical manifestations

Patients with AIDS or medically immunosuppressed patients are the primary target of pneumocystis pneumonia. Patients present with a fever, non-productive cough, and dyspnoea. Pulmonary symptoms could be accompanied by other systemic symptoms like fatigue and weight loss (Kazanjian, 2013; Kovacs, 2012).

Etiological diagnosis

Because pneumocystis cannot be cultured definitive diagnosis requires direct examination of the suitable sample. The preferred sample is sputum. Alternative samples can be obtained by bronchoalveolar lavage (BAL) or biopsy. Direct examination could be made by Giemsa or fluorescein-labelled antibody sample staining. Moreover, molecular PCR assays have been extensively evaluated but currently have a limited availability (Gigliotti and Wright, 2018; Kazanjian, 2013; Kovacs, 2012; Miller and Doffman, 2014).

Treatment

The most common treatment for PCP is trimethoprim-sulfamethoxazole (co-trimoxazole) for 2 to 3 weeks. In the case of patients with intolerance or toxicity to co-trimoxazole, an alternative treatment could be carried out using other combinations of drugs. Alternative effective treatments can be dapsone with trimethoprim, clindamycin with primaquine, or atovaquone alone. In patients with glucose 6-phosphate dehydrogenase deficiency, dapsone, or primaquine should be avoided because of an increased risk of hemolysis. In addition, adjunctive therapy with glucocorticoids could be useful and should be evaluated for patients at risk of respiratory failure (Gigliotti and Wright, 2018; Kovacs, 2012; Miller and Doffman, 2014).

Other fungus infections

Other species of fungus can cause opportunistic infections in specific situations or under special conditions, such as in immunosuppressed patients or pulmonary invasive procedures. Pulmonary infection by *Candida albicans* is very infrequent but some cases have been reported in immunosuppressed patients. Other types of fungus occasionally reported as etiological agents in atypical pneumonias are *Rhizopus*, *Geotrichum*, *Sporothrix*, and *Actinomyces* (Fraser et al., 2006).

Respiratory infections caused by helminths

Helminths are designated as both parasitic and free-living worms. In humans, parasites determine the appearance of zoonoses related to socio-environmental living conditions. They constitute a global public health problem due to the high incidence and endemicity as well as the possibility of generating epidemic outbreaks. There are three mayor types of helminth causing respiratory infections (Table 1) (Cox, 2009; Pérez Arellano and Carranza, 2003; Shah et al., 2016).

Cestodes

Hydatid disease

This disease is a zoonosis of worldwide distribution (OPS, 2011). The most important species that affect humans are *E. granulosus* and *E. multilocularis*. They cause cystic echinococcosis (CE) and alveolar echinococcosis (AE). The disease has a distribution pattern that has remained unchanged for decades and continues to be endemic in many countries in South America, Africa, and Asia, with hundreds of cases being diagnosed annually. The regular deworming of dogs introduced in most countries has decreased human infestation, but the disease continues to be endemic. Hydatid disease integrates the list of diseases that WHO focuses on their elimination and/or control by 2050. New plans for the eradication and control of hydatid disease are continuously implemented, including vaccination and diagnosis in dogs (de Salud, 2015; Wen et al., 2019). *Echinococcus* spp. was traditionally defined as causing CE. However, at least 10 genotypes or strains have been currently recognized by DNA sequencing. The genus *Echinococcus* has the following species: *E. granulosus sensu stricto*, *E. canadensis*, *E. orthepi*, *E. felidis*, *E. equinus*, *E. multilocularis*, *E. oligathra*, *E. vogeli*, *E. shiquicus*. Moreover, without appropriate management, both CE and AE can be chronic diseases, leading to death. The definitive hosts are mainly canines that become infected by ingesting viscera with fertile hydatid cysts containing protoscolices larvae. In the dog's intestine, the larvae transform into adult worms that release eggs and mature proglottids that are eliminated through feces. This also leads to the contamination of the environment in which they are found. The eggs are ingested by an intermediate host (sheep, goats, swine, cattle) forming hydatid cysts mainly liver and lungs (Craig et al., 2007; McManus et al., 2012).

Human infection is produced by accidental ingestion of eggs, mainly in rural areas, where contact with the definitive infected host is recurrent. The ingested eggs hatch in the intestinal lumen, giving rise to oncospheres that, through enterohepatic circulation, reach the first filter, made up of the liver, where 70–90% of the cysts are located. Lung disease, which occurs in 15–20% of cases, can be caused by the arrival of the larvae directly to the lung via the blood or lymphatic route, where its maturation leads to the formation of the pulmonary hydatid cyst. Sometimes, pleuropulmonary invasion occurs by the extension of a hepatic cyst that in its growth can reach the pleural cavity.

The slow growth of the cysts can cause the pulmonary hydatid cyst to remains asymptomatic for years and become a radiological finding during general studies. On radiological images, the pulmonary hydatid cyst appears as a solid, rounded mass, which can sometimes present with the so-called meniscus sign or even as a complete hydro aerial image with the endomembrane floating

Table 1 Three mayor types of helminth causing respiratory infections.

Cestodes (taenia)	<i>Echinococcus granulosus</i>	<i>E. multilocularis</i>				
Trematodes (flatworms)	<i>Schistosoma mansoni</i>	<i>S. haematobium</i>	<i>S. japonicum</i>	<i>S. intercalatum</i> , <i>Paragonimus westermani</i>	<i>P. africanus</i>	<i>P. caliensis</i>
Nematodes (cylindrical worms)	<i>Ascaris lumbricoides</i> , <i>Toxocara canis</i>	<i>T. cati</i> , <i>Necator americanus</i>	<i>N. brasiliensis</i> , <i>Ancylostoma duodenale</i>	<i>A. caninum</i> , <i>Strongyloides stercoralis</i> , <i>Trichinella spiralis</i> , <i>Wuchereria bancrofti</i>	<i>Brugia malayi</i> , <i>Dirofilaria immitis</i>	

inside the cystic fluid. Nonspecific symptoms (cough, dyspnoea) may occur when the cyst reaches a diameter close to 10 cm. Symptomatic patients should be immediately investigated by imaging and serological studies. Rupture of the cyst to the pleural cavity (hydropneumothorax or pneumothorax) or even to the airway (vomiting) may occur, accompanied by symptoms such as fever, cough, and mild to fatal anaphylactic reactions.

Serology is a useful diagnostic test intended to detect antibodies in the serum of patients after surgery or drug treatment. Antigen B and Antigen 5 are widely used, particularly in developing countries, although there are doubts about their effectiveness for clinical detection and screening (Craig et al., 2007; McManus et al., 2012). The sensitivity of serology for the detection of serum antibodies is higher than for the detection of free circulating *E. granulosus* antigens. Current serology for human CE basically studies the earliest immunoglobulin IgG response against native or recombinant B antigen using the enzyme immunoassay (EIA) or western blotting. The definitive diagnosis of echinococcosis is carried out through ultrasonography, tomography, and magnetic resonance imaging (Menghi et al., 2017). The treatment for cure of the disease is surgery but it no averts a recurrence. Taking into account the slow growth, location, and possibility of calcification of the cyst, observation and waiting may be also an option. However, this decision is not supported by systematic studies that define its indication and limitations.

AE is a rare disease, caused by *E. multilocularis*. It is endemic in China, Russia, and in some countries in Europe (Holland, France, Germany). Increases in the fox population have determined the expansion of the parasite into habitually non-endemic areas. The final hosts are foxes, coyotes, and, less frequently, dogs. Humans are an intermediate host and they are accidentally infected via contaminated food or contact with animals. The cysts of AE settle predominantly in the liver, leading to the slow growth of multiple irregular cysts poorly delimited from the rest of the parenchyma. In its growth, it spreads to neighboring organs, and at a distance, by the lymphatic or hematogenous route, it can reach the brain, lungs, etc. Moreover, without treatment, death occurs in 100% of cases. The treatment of choice is surgical but is sometimes supplemented with deworming drugs (WHO, 2020).

Trematodes

Schistosomiasis

Schistosomiasis constitutes a public health problem in tropical and subtropical countries since it frequently affects young populations (OPS, 2011; Pérez-Arellano et al., 2006; Pérez Arellano and Carranza, 2003; WHO, 2002). In Africa, Central and South America the most frequent species are *S. mansoni* and *S. haematobium*, while *S. japonicum* predominates in Southeast Asia, China, and the Philippines. Immigrants and travelers are responsible for imported cases in countries where the disease does not exist.

All *Schistosoma* species have an intermediate cycle in freshwater snails, with humans being the definitive host. The form of contagion is by transcutaneous penetration of the cercariae, the intermediate form of the *Schistosoma*. Inside the body, the larvae develop into adult schistosomes, which live in the blood vessels, where the females lay their eggs. Some of those eggs leave the body with feces or urine and continue the parasite's life cycle, while others. Others become trapped in body tissues, where they cause an immune reaction and progressive organ damage. Two forms of schistosomiasis are recognized: intestinal and urogenital, which are caused by the five main species of *Schistosoma*. However, pulmonary manifestations may occur with early symptoms, during larvae transit through the pulmonary capillaries, or in late stages due to embolization of the pulmonary arteries by *Schistosoma* eggs. In the first stage, respiratory symptoms may appear with dyspnoea, dry cough, and wheezing, accompanied or not by fever. The most significant findings in blood tests are leukocytosis with eosinophilia. Nonspecific and diffuse infiltrates are common in radiological studies of the chest.

In advanced forms of the disease, embolization can cause arthritis of the pulmonary arteries, leading to pulmonary hypertension. Dyspnoea is the most characteristic symptom and on radiology, military-type micronodular infiltrates can be found.

For the definitive diagnosis, it is necessary to find the parasite's eggs in urine or stool samples (Ciddio et al., 2017).

Paragonimiasis

Paragonimus westermani is responsible for most infections, and the definitive host (humans) acquire it by ingesting raw crustaceans infected by larval forms of the parasite (metacercariae). *Paragonimus westermani* has an indirect cycle, with intermediate hosts first in freshwater snails and then in crustaceans (Kuzucu, 2006; OPS, 2011; Pérez-Arellano et al., 2006). Larvae arrive at the lung via migration from the intestine, more particularly through the peritoneal cavity. Once they reach the respiratory system, they perforate the diaphragm and colonize the pleural cavity and then the lungs. Once in the lungs, a fibrous layer forms around the larvae, which then continue their maturation, followed by the laying of eggs in the lung at 6–8 weeks (Pérez Arellano and Carranza, 2003).

In the first phase, infected patients may suffer from abdominal and/or pleuritic pain, which is generally bilateral. During pulmonary migration, irritative cough, chest pain, and blood expectoration appear. In the next phase blood expectoration typically becomes chocolate, and recurrent haemoptysis appears (Gómez-Seco et al., 2011).

Leukocytosis with eosinophilia is the most common laboratory finding in the early stages. Eggs of *Paragonimus* can be found in the expectorated material. Another way to establish the diagnosis in the late phase is through BAL or serological tests (ELISA is available).

Nematodes

Ascariasis and hookworm infections

Ascaris lumbricoides is one of the most prevalent parasites in humans (OPS, 2011; WHO, 2005), with a particular incidence in childhood. The infection is acquired by ingesting eggs present in other humans, food, water, or soil (Pérez-Arellano et al., 2006). Eggs reach the small intestine, releasing larvae that cross the intestinal wall and then reach the lungs via the hematic or lymphatic system. Once in the interior of the alveoli, larvae migrate upwards via the tracheobronchial tree until it reaches the larynx after which they are swallowed. In the digestive tract, larvae complete their maturation to adult worms, producing eggs that will be eliminated with feces. Respiratory symptoms develop in the lung phase of the parasite, between 9 and 12 days after the ingestion of the eggs (Coello Kuon Yeng and Rey Guevara, 2019; Dall'Orso et al., 2014). Infections are characterized by transient eosinophilic pulmonary infiltrates, called Löffler's syndrome. *A. lumbricoides* is the main cause of this syndrome worldwide. Symptoms such as irritative cough, retrosternal pain, and mild hyperthermia are frequent findings. Dyspnoea, and hemoptoic expectoration can occur in more severe cases. Approximately 50% of patients present crackling rales and wheezing, and urticaria may appear in the first 4–5 days after respiratory expression of the disease. Hepatomegaly may appear in some patients. The above-mentioned acute symptoms are usually self-limiting and generally remit in 5–10 days (Dall'Orso et al., 2014). Radiological findings consist of small rounded or oval infiltrates in both lung fields. These infiltrates are migratory, and generally disappear after several weeks. Worms produce irritation of the intestinal mucosa by mechanical action. The formation of tangles can lead to intestinal obstruction. At the respiratory system level, larval migrations induce TH2-type responses with increased IgE, IgG, and eosinophils; a decrease in TH1 lymphocytes favors susceptibility to bacterial infections. The increase in IgE favors infections by reducing the action of polymorphonuclear cells (PMN). In the liver and lung, larvae and their antigens determine a granulomatous reaction with central necrosis that facilitates the entrapment of bacteria and the formation of abscesses.

The definitive diagnosis of ascaris pneumonitis depends on the isolation of their larvae in respiratory secretions or gastric aspirate.

Ancylostoma duodenale and *Necator americanus* (OPS, 2011; Pérez-Arellano et al., 2006; Pérez Arellano and Carranza, 2003) are common causes of disease throughout the world. Its larvae enter via the skin or orally. Larvae migrate through lungs causing a hypersensitivity response, and symptoms similar to those caused by *Ascaris*.

Strongyloidiasis

Strongyloides stercoralis infection in humans occurs via penetration of larvae through the skin due to walking or working barefoot in places contaminated by human feces. Larvae enter the body and are carried via the blood into the lung. From the alveoli, they ascend to the airways, including the upper ones, where they are swallowed (Mascarini-Serra, 2011; OPS, 2011; Pérez Arellano and Carranza, 2003).

In the digestive tract, larvae turn into adult worms. The eggs produced by adult worms are eliminated through feces or they hatch into larvae that restart the cycle through the intestinal lumen. The latter is responsible for recurrent infections (self-infection) (Pérez Arellano and Carranza, 2003).

Transpulmonary larval migration can produce dry cough, pharyngeal irritation, dyspnoea, wheezing, and haemoptysis. Some patients with chronic strongyloidiasis experience recurrent episodes of fever and pneumonitis, asthma attacks (which worsen, paradoxically, with the use of corticosteroids) or dyspnoea due to restrictive disease pulmonary. The definitive diagnosis of pulmonary strongyloidiasis is based on the finding of larvae in sputum or BAL.

Trichinosis

This parasitosis is acquired by ingesting raw or semi-cooked meat, which in most cases is pig meat infected with *Trichinella spiralis* larvae (OPS, 2011; Pérez-Arellano et al., 2006). Trichinosis has an intestinal phase, followed by a muscular phase with encystment of larvae that remain viable for prolonged periods of time.

Pulmonary involvement occurs first by the passage of larvae through the pulmonary circulation and then by myositis of the main and accessory respiratory muscles (Valle-Velazco González, 2005).

In the first stage, symptoms are nonspecific (irritative cough) and radiology bibasal infiltrates that spontaneously resolve can be found. In the stage of myositis, deterioration of respiratory function, chest pain, and dysphonia may occur. Calcified intramuscular cysts are visible on a chest radiograph. A definitive diagnosis is based on the presence of larvae in a muscle biopsy.

Visceral larva migrans or toxocariasis

Visceral larva migrans or toxocariasis is a prevalent disease in childhood, especially in areas with high infestation of dogs and cats by *Toxocara canis* and *T. cati*. Humans are not a definitive host for this parasite and human infection occurs due to contact with infected

animals or by ingestion of soil contaminated by canine or feline feces (Mascarini-Serra, 2011; OPS, 2011; Pérez-Arellano et al., 2006). In the lung, larvae cause the formation of eosinophilic granuloma. Chronic cough and bronchospasm are common symptoms, as well as Löffler's syndrome and asthma attacks and/or wheezing. Radiology shows poorly defined consolidations and laboratory shows are characterized by leukocytosis with eosinophilia, increased IgE, and a positive ELISA. Rheumatoid factor and hypergammaglobulinemia may also be found.

T. canis does not complete its life cycle in the human and does stool examinations are negative. Hence, a definitive diagnosis is established by identifying larvae in biopsy samples.

Tropical pulmonary eosinophilia (filariasis)

The causal agents, *Wuchereria bancrofti* and *Brugia malayi*, are inoculated into humans (the exclusive host) by the bite of mosquitoes (*Culex quinquefasciatus*, *Aedes*, and *Mansonia*) that inoculate larvae. These larvae spread lymphatically and are mostly trapped in the lungs (OPS, 2011; Pérez-Arellano et al., 2006; Valle-Velazco González, 2005). At the respiratory level, affected patients usually develop a dry, nocturnal cough, and episodes of bronchospasm. Concomitantly, dyspnoea and weight loss appear.

Typical laboratory findings include leukocytosis with eosinophilia, a rise in IgE, and the presence of eosinophilic alveolitis in BAL. Antifilaria antibody test is positive. In chest radiography, there may be inhomogeneous opacity with a nodular reticulum pattern (up to 5 mm in diameter) and there may be a restrictive effect in the functional respiratory study (World Health Organization, 2014).

Dirofilariasis (heart worm)

Dirofilaria immitis is transmitted from dog to human through the bite of mosquitoes of different species and genera belonging to different parts of the world. Examples of such mosquitoes include *Culicidae*, *Anopheles*, and *Aedes* (OPS, 2011; Pérez-Arellano et al., 2006; Valle-Velazco González, 2005). The infection is not transmitted from person-to-mosquito-to-person nor from person-to-person because humans are "dead-end" hosts (Sileli et al., 2016). In the lung, infection can induce vasculitis of the pulmonary arteries if the worm lodges in its immature form in the right ventricle. The patient may be asymptomatic or present nonspecific symptoms: cough, fever, chest pain, and dyspnoea. The development of pulmonary nodules is considered to be due to an inflammatory reaction against the deadly parasite. On radiology, it appears as a solitary nodule on the periphery of the lung. It does not require specific treatment but should be considered as a differential diagnosis in the study of pulmonary nodules.

Respiratory diseases caused by protozoa

Amoebiasis

Entamoeba histolytica is a worldwide protozoan that is transmitted to man through contaminated food and water. Two stages are recognized in its life cycle: the invasive vegetative form amoeboid (trophozoite) and the cystic resistance and infective form (OPS, 2011; Valle-Velazco González, 2005). Amoebiasis has worldwide distribution and transmission occurs via ingestion of mature cysts present in contaminated food and water.

The main organ affected by *Entamoeba histolytica* is the intestine, causing amoebic dysentery. However, it also has extra-intestinal locations that affect the liver and lung (Cox, 2009). In this case, the infection can reach the thorax through blood from the primary intestinal lesion, or a liver abscess that, when it extends to the subdiaphragmatic space, reaches the pleural cavity or lung tissue. In the first case, it causes empyema and in the second a lung abscess. Other less frequent forms are hepatobronchial or biliopulmonary fistula. These conditions are always very serious, life-threatening situations that require urgent treatment. Clinical findings are supplemented through laboratory investigation of amoebic antigens by ELISA and PCR.

Malaria

Malaria is a life-threatening disease caused by parasites transmitted to humans by the bite of infected female mosquitoes of the genus *Anopheles*. It is a preventable and curable disease (Jiménez et al., 2005; OPS, 2011; WHO, 2019).

According to WHO data, more than 200 million people were infected with malaria during 2018. The disease has a high incidence in Africa, mainly affecting children under 5 years of age. The species causing malaria are *Plasmodium vivax*, *P. malariae*, *P. ovale*, *P. falciparum*, and *P. knowlesi*.

The biological cycle of malaria

Plasmodium needs two hosts to complete its cycle. During the hematophagy process, the female *Anopheles* mosquito inoculates the sporozoites into the human. Sporozoites infect liver cells and multiply by schizogony, leading to the formation of merozoites. After multiplication in the liver (exoerythrocytic schizogony), the parasite invades the red blood cells and reproduces by schizogony (erythrocytic schizogony). Merozoites invade red blood cells. Annular trophozoites become schizonts that will give rise to new merozoites. Some parasites are sexually differentiated (gametocytes). When the parasite is in the blood, the clinical manifestations of the disease appear. Male (microgametocyte) and female (macrogametocyte) gametocytes are ingested by an *Anopheles* mosquito during hematophagy. The multiplication of the parasite in the mosquito is known as the sporogonic cycle. Microgametes fertilize

macrogametes and develop zygotes. The zygote becomes a mobile ookinete, invades the wall of the intestine, and becomes an oocyst. The oocyst develops sporozoites inside, which once released ascend to the salivary glands. Inoculation of sporozoites into a new host perpetuates the malaria cycle.

In general, lung involvement is part of a general systemic affection, with high parasitemia, multiple organ failure, and severe acute respiratory distress. The diagnosis of malaria is based on the finding of plasmodium in a thick drop of blood. Species differentiation however requires a fine drop of blood.

Introduction

Thousands of human viruses challenge human life daily by affecting virtually any anatomic site or function. The urinary tract is no exception. Urologic practice copes frequently with bacterial urinary tract infections (UTIs), but most Urologists are not familiar with urinary infections of viral origin. These are usually seen in immunocompromised patients, especially in solid organ and stem cell transplantation recipients.

While it is assumed that no bacteria should be found in the urine of healthy people, especially in men, some viruses can be found in healthy, asymptomatic, and immunocompetent patients. For example, the polyomaviruses JC virus (JCV) and BK virus (BKV) infect the majority of humans asymptotically, but are an increasing cause of morbidity and mortality in immunocompromised patients. The prevalence of BKV and JCV infection ranges from 65% to 90% and from 20% to 60% in the adult population, respectively (Knowles, 2006). Despite this difference in prevalence, JCV is more commonly found in the urine of healthy adults, making BKV excretion a more sensitive indicator of immune status. Therefore, the presence of an identifiable viral organism with inflammatory symptoms is required to define a viral infection.

Viral infections can cause clinical syndromes of the lower (bladder) or upper urinary tract (kidneys, ureters). The most common presentation is hemorrhagic cystitis. The clinical frame and the natural history of UTIs depend on anatomic abnormalities and more importantly on the immunologic status of the host. Whereas mortality among healthy patients with UTIs is extremely low, viral UTIs with high viral load can result in multiorgan failure and high risk of mortality in immune-compromised patients. The kidneys can also be the target of several glomerular syndromes associated with chronic (HBV, HCV, HIV) or acute/subacute (Dengue, Hantavirus, etc.) viral infections through a direct or immune-mediated injury. As a final topic, the involvement of the urinary tract by a SARS-CoV-2 infection is investigated. The aim of this chapter on viral UTIs is to present an overview and to provide a practical approach supporting clinical decisions.

Epidemiology

Recent diagnostic improvements led to identify viruses in many more clinical settings as compared to the past. As such, it was found that viral infections are a common cause of hemorrhagic cystitis. Hemorrhagic cystitis is the most common presenting symptom of viral UTI. Hemorrhagic cystitis is a well-recognized complication of hematopoietic stem cell transplantation (HSCT) with an incidence of 15–25%. It comprises a wide range of symptoms varying between microscopic hematuria and severe hemorrhage.

In a large series of 407 adult patients undergoing allogeneic HSCT, hemorrhagic cystitis was viral-induced in 87.5% (Dosin et al., 2017). Similarly, in a prospective study of more than 102 children undergoing bone marrow transplantation, a viral cause was identified in all children with hemorrhagic cystitis (Gorczyńska et al., 2005).

Although the prevalence is lower than in bone marrow transplantation recipients, renal transplantation is another setting for viral UTIs. Human polyomavirus, Adenovirus, and Citomegalovirus, account for the vast majority of viral infections.

Polyomavirus

Polyomaviruses are small, non-enveloped viruses, which are widespread in nature and highly adapted to grow in the species and the tissue they infect. BK and JC viruses are human polyomaviruses infecting most people throughout the world, as shown by the presence of antibodies against viral proteins in about 80% of the human population (Pinto et al., 2014).

BK virus (BKV)

Polyomavirus primary infection occurs during childhood in 60–100% of general population, with approximately 97% of the adult population having antibodies against it (Demeter, 2000). BK Virus (BKV) has a significant homology to JCV, a neurotropic virus causing progressive leukoencephalopathy. It can be acquired through a respiratory or oral route. While the primary infection is usually asymptomatic, the virus seeds the urinary system and the brain, often remaining in a latent form (Shah, 2000). BKV has a urotheliotropic nature and can be identified in the epithelium of the collecting ducts and of the transitional tissue. Extensive experience over the past 3 decades has shown the prevalence and clinical importance of BKV reactivation in patients with bone marrow transplantation (BMT) and solid organ transplantation. The first evidence of BKV in BMT was reported in 1981, with the detection of BKV in the urine of 13 patients, 1 to 6 weeks after transplantation. The typical cytopathologic changes of BKV are often found in a healthy person, and it is believed to represent transient shedding of virions in urine, most likely secondary to stress or decreased immune response. The patient's cytopathologic changes resolve within 3 months, and there seems to be no clinically significant sequelae of BKV-positive cytology in immunocompetent people. Different disease processes have been linked to BKV infection, but the two most important diseases are polyomavirus-associated nephropathy (PyVAN) affecting kidney transplant patients and polyomavirus-associated hemorrhagic cystitis (PyVHC) affecting allogeneic hematopoietic stem-cell transplantation (HSCT) patients. Other pathological processes that have been associated with BKV are ureteric stenosis, encephalitis, meningoencephalitis, pneumonia, vasculopathy and bladder cancer. The following sections are dedicated to BKV-related syndromes affecting the urinary tract.

a) *Polyomavirus-associated hemorrhagic cystitis (PyVHC)*

Hemorrhagic cystitis (HC) is a frequent complication after HSCT. According to the time of occurrence after HSCT, HC is defined as early- and late-onset. Early-onset HC occurs typically during or within 48 h after the end of conditioning regimen, and it is the result of a direct toxic effect of drug metabolites and radiotherapy on the bladder mucosa. Late-onset HC usually starts around the time of the period of neutrophil engraftment (weeks 2–4) or in second-third month after HSCT (Hirsch and Pergam, 2016a, b). The concurrent presence of prohemorrhagic abnormalities of coagulation, severe thrombocytopenia and mucosal inflammation are predisposing factors for any type of HC.

The pathogenesis of BKV is not well understood as similarly high urine BKV loads are found in kidney transplant patients, most of whom do not develop cystitis or gross hematuria (Funk et al., 2008; Leboeuf et al., 2017). Rather, a sequence of events has been suggested, starting with subclinical urothelial damage by the conditioning regimen, high-level BKV replication leading to viral denudation of the pre-damaged regeneration-impaired urothelial lining and urinary leakage in the submucosa followed by hemorrhagic exacerbation with abundant inflammatory cell infiltrates following allogeneic stem cell engraftment (Bedi et al., 1995; Li et al., 2013). Indeed, conditioning involving cyclophosphamide, busulfan and total body irradiation has been implicated, and the pronounced toxic, inflammatory properties of cyclophosphamide and its metabolite acrolein are supported by clinical and experimental studies (Romih et al., 2001).

Adenovirus, JCV, citomegalovirus (CMV) and other infectious (bacteria, parasite) and non-infectious etiologies (bleeding disorders with or without low platelet count, primary or metastatic neoplasia, vesical catheter or ureteric stenting) may also cause hemorrhagic cystitis, and must be excluded for appropriate diagnosis and management (Hirsch and Pergam, 2016a, b). The severity of hematuria is commonly described as microscopic (grade 1); macroscopic (grade 2); macroscopic with clots (grade 3); or macroscopic with clots and postrenal failure secondary to urinary tract obstruction (grade 4).

b) *Polyomavirus-associated nephropathy (PyVAN)*

The first reports describing disease resembling polyomavirus-associated nephropathy (PyVAN) in kidney transplant patients, came as early as 1978 (Coleman et al., 1978). However, it was not until the late 1990s that PyVAN emerged and that BKV was found to be its etiologic agent (Binet et al., 1999). At that time, new and more potent immunosuppressive regimens were being taken into use, capable of decreasing the rejection rates at the expense of increased risk of opportunistic infections like BKV. PyVAN affects between 1 and 10% of kidney transplant patients during the first 2 years post-transplantation. PyVAN rarely affects patients other than kidney transplant recipients, and so far only 26 cases of biopsy confirmed PyVAN, in native kidneys of other immunocompromised patients, have been reported (Sharma et al., 2013). This clearly suggests that there must be risk factors associated with the allograft and not only with the suppressed immune status. Prognostication is complicated by the many putative risk factors, including HLA-mismatch, donor gender (female) and age (high), recipient of male gender, type and dose of immunosuppressive medication and transplantation events such as ureteric stents, steroid exposure and acute rejection (Brennan et al., 2013). The pathogenesis of PyVAN is characterized by high-level BKV replication in the renal-tubular epithelial cells of the transplanted kidney leading to cytopathogenic loss and thereby denudation of the epithelial monolayer in the allograft tubulus. As a consequence, the virus leaks into the tissue and bloodstream and inflammatory cells infiltrate the interstitium leading to tubular atrophy and interstitial fibrosis. This reduces the graft function and increases the risk of graft loss. Of note, the urothelial cells may also play an important role in PyVAN. Mathematical modeling of BKV replication in kidney transplant patients with PyVAN suggests that viral replication starts in the renal tubular epithelial cells but is then carried to the urothelial cell compartment where more than 90% of urine BKV loads are generated (Funk et al., 2008). This is supported by histopathologic data revealing extensively infected urothelial cells in the bladder of patients with PyVAN. In agreement with this, primary human urothelial cells from bladder were found to be very permissive to BKV infection.

c) Ureteric stenosis

BKV was first identified in the urine of a renal transplantation recipient with the initials B.K. by Dr. Sylvia Gardner in 1971: the kidney transplant patient from whom BKV was initially isolated, was suffering from ureteric stenosis (Gardner et al., 1971). Since then, there have been several reports on BKV-associated ureteric stenosis, usually in kidney transplant patients, both pediatric (Rajpoot et al., 2007) and adult (Coleman et al., 1978) but also in allogeneic HSCT patients (Hwang et al., 2013). The pathogenesis of ureteric stenosis is still not completely resolved. Coleman suggested in 1978 that high-dose steroids, given to kidney transplant patients post-transplantation, permitted reactivation of BKV (Coleman et al., 1978). The ureteric epithelium which was damaged by ischemia or inflammation supported infection and was replaced with granulation tissue. In a study of kidney transplanted cynomolgus monkeys receiving immunosuppression, a reactivation of a new polyomavirus called cynomolgus polyomavirus occurred in 12–57 monkeys (Van Gorder et al., 1999). The virus was detected in the urothelium of graft ureters in association with inflammation and in the smooth muscle cells of the ureteric wall showing signs of apoptosis. A significant incidence of late onset stenosis was seen. Apparently, ureteric stenosis is now less frequently reported, possibly due to better surgical techniques and a decline in the use of ureteral stents (Hirsch, 2005).

JC virus (JCV)

BKV and JCV have been shown to establish latency in several tissues including the urinary system. In renal transplant patients and more generally in those suffering from immune system impairments, human polyomaviruses can on rare occasions cause tubulo-interstitial nephritis. Nevertheless, data regarding the ability of JCV to induce ureteral and bladder damage are very scarce (Di Maida et al., 2021). The triggering mechanisms for JC virus reactivation are not well defined yet. It has recently been suggested that there is a higher risk of JC virus reactivation in immunocompromised patients and those treated with immunomodulatory drugs for chronic inflammatory disorders, hematological malignancies, or following organ transplantation (Kartau et al., 2019). However, drug specific causality is difficult to assess, since most patients receive multiple immunomodulatory medications concomitantly or sequentially, or present with several immunocompromising factors related to their underlying disease. At the level of the urinary tract, the association between patient immune status and JCV pathogenicity appears even more ambiguous, due to the limited available evidence. Moreover, low levels of JC viruria can also occur in approximately 13–20% of healthy individuals (Boukhoum et al., 2016), making the interpretation of data even more difficult.

The central nervous system and kidney are considered as the reservoirs of JC virus infection, in which the virus can persist in latency after primary infection. The possible role of JC virus in urinary tract involvement has only recently been recognized. Based on laboratory findings and PCR studies, several authors have long considered BK virus as the only polyomavirus eventually affecting the kidneys and urinary tract. Indeed, although genomic sequences of both JCV and BKV DNA have been detected by PCR in renal biopsies of transplanted patients, combined immunohistochemical and molecular biology studies suggested that renal impairment was secondary to the replication of BK virus, whereas JC virus was usually present as a co-infecting agent in a latent, non-replicative phase (Boldorini et al., 2001). As such, JC virus has long been considered unable to elicit pathological effects.

Nickeleit et al. (2000) proposed that JC viral particles produced after a viral lytic cycle in the renal pelvis or ureter may enter the capillary vessels and infect the tubular cells of the kidney or, alternatively, follow an ascending route of infection from transitional cells to kidney tubular cells. Conversely, Boldorini et al. (2003) first reported morphological evidence of lytic JC virus infection in four renal specimens from AIDS patients, supporting the hypothesis that, in immunocompromised patients, active JC viral replication can also occur in the kidney and urinary tract. JC virus-related nephropathy is now recognized as a rare cause of nephropathy in transplant recipients (Wiegley et al., 2021). Ureteral and bladder involvement is more rarely reported in different types of immunosuppressed patients (Cavallo et al., 2007).

Diagnosis of polyomavirus

As the initial presentation of PyVAN is insidious, it is strongly recommended to screen kidney transplant patients regularly for early diagnosis (Hirsch, 2005). Screening should be performed at least every 3 months the first 2 years after transplantation and then annually until the fifth year of post-transplantation. Screening is usually accomplished by quantitative PCR of urine and/or plasma for detection of high-level BKV viruria $\geq 7 \log_{10}$ copies/mL or viremia $\geq 4 \log_{10}$ copies/mL (Randhawa et al., 2004). Alternatively, cytological examination of urine in search of decoy cells (Mackenzie et al., 1978) or electron microscopy in search of viral aggregates can be performed (Singh et al., 2009). Plasma PCR has a higher positive predictive value than urine PCR as episodic viruria is quite frequent in this patient group, while viremia is less common and usually precedes PyVAN. Usually the diagnosis of PyVAN requires a histological demonstration of BKV replication (Purighalla et al., 1995). However, due to the focal nature of PyVAN, a negative biopsy result cannot rule it out (Hirsch and Pergam, 2016a, b; Brennan et al., 2013). To distinguish PyVHC from the more frequent early-onset hemorrhagic cystitis occurring prior to the engraftment due to urotoxic conditioning or total body irradiation, the triad of cystitis, hematuria (grade II or more) and high-level BKV replication with urine loads of $\geq 7 \log_{10}$ GEq/mL, must be present.

Treatment of polyomavirus

No specific anti-viral therapy has been developed to treat PyVAN. Thus, early treatment before the development of irreversible histopathological damage are important to ensure a favorable prognosis. The AST (American Society of Transplantation) guideline recommends starting interventions at the high-level BK viremia stage, which is indicative of probable or presumptive PyVAN (Hirsch et al., 2019). Since no BKV-specific antiviral therapy has been developed, reducing the level of maintenance immunosuppression is the most common and effective treatment for BK viremia or PYVAN. Currently, the AST guideline recommends two strategies (Hirsch et al., 2019): (1) first reduce the dose of the calcineurin inhibitor by 25–50% in one or two steps, and then reduce by 50% and ultimately discontinue the antimetabolites; (2) first reduce the antimetabolites by 50%, and then reduce the calcineurin inhibitors by 25–50% and discontinue the antimetabolites. At this time, the “calcineurin inhibitor first” and “antimetabolite first” approaches (as the first step) are considered largely equivalent (Hirsch et al., 2019; Bischof et al., 2019; Hardinger et al., 2010).

In addition, several medical treatments have been tried, including intravenous immunoglobulin (Piburn and Al-Akash, 2020), cidofovir (Kuten et al., 2014), and fluoroquinolone (Gabardi et al., 2010). Cidofovir (Vistide®, Gilead, Foster City, CA, USA), is an intravenously administered nucleoside analog of deoxycytidine monophosphate that is licensed by the U.S. Food & Drug Administration for the treatment of cytomegalovirus (CMV) retinitis in AIDS patients. In 2000, a patient with PyVHC and simultaneous CMV infection was successfully treated with cidofovir and shortly after it was reported to be useful in the treatment of one patient with PyVAN (Bjorang et al., 2002). The drug is taken up via the organic anion transporters (OAT1), which are mainly expressed on the basolateral side of renal tubular epithelial cells. Cidofovir is nephrotoxic and has less potent anti-BKV activity than the other therapies. Intravenous immunoglobulin through osmotic injury causes vacuolation in proximal tubular epithelial cells, in turn leading to acute kidney injury (Levy and Pusey, 2000). Fluoroquinolones are synthetic broadspectrum antimicrobial agents targeting the bacterial enzymes topoisomerase II and IV (158) and are also suggested to interfere with the helicase activity of BKV LTag (Ali et al., 2007). Critical aspects of Fluoroquinolone in this setting are related to their gastrointestinal and central nervous system side effects, given the lack of significant effects on BKV replication and hemorrhagic cystitis severity, and the selection of antibiotic resistance (Walker, 1999). None of these treatments have sufficient clinical data supporting their use as standard practices. PyVAN sometimes accompanies acute rejection; these cases are difficult to treat. Due to the lack of effective anti-viral drugs, the main therapeutic strategy is to reduce immunosuppression; at the same time, clinicians must pay attention to the risk of allograft rejection.

Therapy for PyVHC is purely supportive, involving symptom relief by analgesia, hyperhydration to increase diuresis and continuous bladder irrigation to prevent clot formation and urinary tract obstruction (Hirsch et al., 2019). Moreover, lost platelets and erythrocytes are substituted. Other treatments of PyVHC aim at repair and regeneration of the urothelial mucosa through hyperbaric oxygen therapy or by topical application of fibrin glue. The main drawback of hyperbaric oxygen is its limited availability on a larger scale, the requirements for dedicated hyperbaric room facilities, the risk of ear barotrauma/pressure intolerance and claustrophobia linked to the procedure (Hosokawa et al., 2014). Finally, topical applications to the damaged bladder mucosa to achieve hemostasis through cystoscopy have been reported in single-center retrospective series of 35 patients. The complete response rate was 83% (Tirindelli et al., 2014). Similarly, several compounds to reduce bleeding have been used in case studies and small series, e.g. FXIII concentrate (Demesmay et al., 2002), intravesical sodium hyaluronate (Cipe et al., 2009), estrogens (Ordemann et al., 2000) or choreito extract granules (Kawashima et al., 2015). The same adjuvant treatments have been tried for PyVHC as for PyVAN again without any documented benefit.

As the understanding regarding the pathogenesis of PyVHC is evolving, new potential therapeutic targets are expected to emerge. Recently, Schneidewind et al. reported the successful use of an innovative three-dimensional (3D) organotypic cell culture model for studying BKV life cycle. Such culture methods will highlight the interactions between BKV and human urothelial cells which might unveil the unknown nuances associated with BKV pathogenesis. Furthermore, they might facilitate the in vitro testing of antiviral drugs against new potential therapeutic targets (Schneidewind et al., 2020a, b).

In a recent experimental study, a novel 3D cell culture approach was used to study BKV pathogenesis and potential new therapeutic targets. The results favored the involvement of the STAT3 pathway in the pathogenesis of BKV infection, and IL-11 was recognized as the potential therapeutic target. The utilization of antibody against IL-11 showed promising in vitro activity against

BKV. Although tocilizumab (an anti-IL-6 antibody) did not yield significant results in this study, its role in the treatment of BKV infection will need detailed further exploration, as IL-6 is an important component of the STAT3 pathway (Schneidewind et al., 2020a, b). Likewise, it may be expected that further experimental studies focussed on the STAT3 pathway in BKV infection might unveil more potential therapeutic targets.

Synopsis and current recommendations on BKV management

Polyomavirus BK persistently infects the majority of people at an early age, usually without causing disease. Pathological consequences appear mainly in immunodeficient individuals, an expanding patient group due to transplantations, use of immunosuppressive therapy and the increasing average age of the population. However, the management of PyVAN and PyVHC differs.

Safe and effective antiviral treatment of BKV diseases is still lacking and for patients with PyVAN, the only treatment strategy with documented effect is reduction of immunosuppressive therapy. On the other side, PyVHC remains a challenging complication after allogeneic HSCT with average rates of 13%. Its diagnosis requires the clinical and laboratory triad of cystitis, gross hematuria and high urine BKV loads $7 \log_{10}$ copies/mL, but a significant role of other etiologies must be excluded. Plasma BKV loads 1000 copies/mL has a role for the management and follow-up of triad positive allogeneic HSCT recipients. Screening of asymptomatic HSCT patients at risk remains an area of investigation and is presently not recommended, as pre-emptive therapy is not established (DII). Specific antiviral prophylaxis is not available and fluoroquinolones are not recommended. PyVHC treatment is based on the best supportive therapy, such as hyperhydration, bladder irrigation, platelet transfusions as needed to reduce bleeding, and pain treatment, particularly when using myeloablative conditioning based on cyclophosphamide, busulfan and total body irradiation. The risk/benefit ratio of reduction of immunosuppression is not clear in PyVHC and must be balanced with the risk of worsening or triggering an acute graft-versus-host disease. Antiviral treatment with intravenous cidofovir is controversial due to the absence of randomized controlled studies. Until the availability of safe and effective antivirals, the use of cidofovir may be an option although there is uncertainty of efficacy, the best dose schedule and the need to balance any benefit against its renal side effects. Non-specific measures aimed at speeding the healing process of the damaged urothelial lining such as hyperbaric oxygen therapy or urologic fibrin glue application have been successful in a limited number of uncontrolled studies. No recommendation is possible for several other treatments such as the administration of intravesical sodium hyaluronate, intravenous FXIII concentrate, leflunomide, estrogens, mesenchymal cells and cellular immune therapy because these treatments have only been used sporadically in a very limited number of patients or are still experimental. These evidence-based recommendations are applicable for both pediatric and adult patients. In conclusion, despite much progress in understanding the pathogenesis, epidemiology and risk factors of PyVHC, this complication still represents a disabling unmet clinical need with limited prophylactic and therapeutic options. To overcome this deficiency will require novel antiviral treatment approaches supported by proper clinical trials.

Our institutional BKV protocol in transplanted patients

BKV PCR-based search is performed every 3 months in the first year post-transplantation, every 6 months in the second year, and annually thereafter.

In case a billion copies/mL is found in the urine, BKV is searched in the blood. The threshold for an active treatment is a BKV plasma level of $5 \log_{10}$ copies/mL. The search for SV40 on renal tissue is also performed in order to quantify the renal injury.

Our strategy in case of clinically significant BKV infection is based on three progressive steps:

- 1) reduction or suspension of antimetabolite therapy (mycophenolate)
- 2) switch calcineurin-inhibitor therapy from tacrolimus to everolimus
- 3) antiviral therapy with levoflunamide, in case the above steps were ineffective

Adenovirus

Adenoviruses (ADV) are double-strand DNA viruses with at least 51 serologic subtypes. They are known to cause upper respiratory, gastrointestinal, and conjunctival infections in healthy people and children; however, their pathogenicity is altered by the immunologic status of the host, and in immunocompromised patients, ADV can affect many other systems (Ison, 2006). Human ADV are classified into 7 species (A–G) and 67 types (1–67). Types 1–51 were identified by serotyping, whereas types 52–67 were identified by genomic sequencing and bioinformatic analysis. As the assay for ADV detection covers only a proportion of the currently known virus types, the occurrence of ADV infection of the urinary tract may have been underestimated. In addition, ADV has been identified as the causative agent of various diseases, including acute upper respiratory inflammation, pneumonia, pharynx conjunctivitis, gastroenteritis, hepatitis, and myocarditis (Echavarria, 2008). Normally, ADV causes asymptomatic infection of lymphoepithelial tissues, but in the immunocompromised patient, they can reactivate the latent infection or cause de novo infection. The adenoviral infections are more common in stem cell transplantation and solid organ transplantations. ADV can be detected in 10% of urine samples after transplantation, and over 12 months of follow-up, adenoviral UTIs occurred in 9% of patients (Runde et al., 2001). ADV are ubiquitous infectious agents that cause significant morbidity and even loss of life, particularly in select groups of at-risk individuals. Troubling outbreaks of ADV infection occur far too frequently, and these can also affect otherwise healthy individuals not normally at risk for serious infection.

Diagnosis

Adenoviral cystitis can present as gross or microscopic hematuria in up to 20% of patients (Allen and Alexander, 2005). History of solid organ or bone marrow transplantation and use of immunosuppressants aids in diagnosis because ADV cystitis occurs almost exclusively in immunocompromised patients. Most cases of ADV-related hemorrhagic cystitis occur within 12 months of transplantation (Hofland et al., 2004). The adenoviral infection can often coexist with Aspergillosis and CMV in immunocompromised patients, and broad cultures should be obtained. A urine bacteriological culture, urine cytology, and the presence of urine ADV and BKV DNA were examined in those with a diagnosis of urinary tract infection based on symptoms of macrohematuria and dysuria (i.e., urinary frequency, urgency, and micturition pain). A definitive diagnosis of ADV infection of the urinary tract should be confirmed by positive results for the presence of ADV DNA in the urine. In addition, blood culture and the presence of ADV DNA in the blood were examined in patients with fever. ADV DNA in the urine and blood is detected using a qualitative polymerase chain reaction assay (Lion, 2014) for ADV types 1–6, 8, 19, and 37; types 7 and 11 were also included because of hemorrhagic cystitis. BKV DNA in the urine is also detected using a qualitative polymerase chain reaction assay. Furthermore, it is necessary to perform a cystoscopy, computed tomography (CT), and/or magnetic resonance imaging (MRI) of the abdomen and pelvis in cases of prolonged hematuria, and renal graft biopsy in cases of renal graft dysfunction.

Treatment

Unfortunately, until recently there was no single antiviral drug that would be potent and devoid of drug toxicity. For treatment of ADV infection of the urinary tract after renal transplantation, reduction in immunosuppression is necessary, similar to other viral infections (Asim et al., 2003). Both B and T lymphocytes play an important role in recovery from ADV infection. Therefore, if clinical improvement cannot be achieved by the reduction or discontinuation of mycophenolate only, dosages of calcineurin inhibitors, such as tacrolimus or cyclosporine, should be reduced. Moreover, an antiviral effect can be expected following intravenous immunoglobulin administration, particularly in cases of hypogammaglobulinemia. Antiviral therapies include CDV, ganciclovir, ribavirin, and brincidofovir. The primary anti-viral agent for the treatment of ADV infections is CDV. Cidofovir can display a dose-limiting nephrotoxicity, and the incidence is relatively low (6.9%). Intravesical administration of cidofovir achieved favorable outcomes in case of non-response to intravenous cidofovir or renal failure.

The findings also suggested that this method could be an alternative to intravenous administration of cidofovir to reduce nephrotoxicity. Owing to less nephrotoxicity and high potency against all clinically significant ADV subtypes, brincidofovir is an attractive antiviral therapy for the management of ADV disease (Painter et al., 2012). However, given the small sample size, more studies are expected to provide important evidence for the efficacy of brincidofovir (Lion et al., 2010). An appreciable benefit among patients with various manifestations of ADV disease was found to be associated with ribavirin, although the small number of cases in the studies limits these conclusions. Based on current data, there is no recommendation regarding the use of ganciclovir for ADV systemic infection but there is possible benefit of ganciclovir against urinary tract infection. Previous study observed that hemorrhagic cystitis and nephritis probably can generally be treated only with reduction in immunosuppression without specific antiviral therapy (Florescu et al., 2013).

The realization that we need more effective and safer antiviral drugs for HAdV infection seems to have passed a critical threshold in recent years, and the surge of studies in the field of anti-ADV development is encouraging. The past decade has seen exponential growth in the field of ADV antivirals. However, there is still ground to be covered before an effective therapy is clinically available. Progress in this field is intimately related to the strength and power of the tools available. Specifically, drug screening platforms and model organism systems for preclinical testing are critical tools to advance research on ADV antivirals (Mackenzie et al., 2021). In conclusion, although urinary tract infection is a common complication after renal transplantation, a differential diagnosis of ADV infection should be considered. ADV infection can be cured, although nephritis or viremia might be developed. Hence, the possibility of exacerbation should always be considered. After a definitive diagnosis of ADV infection of the urinary tract, adequate follow-up observation should be conducted, and diligent and aggressive therapeutic intervention is required before the condition worsens.

Cytomegalovirus

Cytomegalovirus (CMV) infection is common, and more than 60% of adults are seropositive. CMV belongs to a large group of herpes viruses with limited pathologic significance in immunocompetent patients. CMV reactivation or new infection is common in transplantation patients, and it can cause significant mortality and morbidity; hence CMV prophylaxis is commonly employed in patients after transplantation. CMV is a relatively rare cause of lower UTIs; however, circumferential evidence supports the association between CMV and hemorrhagic cystitis (Spach et al., 1993). Although rare, CMV cystitis can also occur in immunocompetent patients (Basquiera et al., 2003). Hemorrhagic cystitis has been clearly associated with reactivation of CMV (Childs et al., 1998). CMV is also believed to cause ureteritis and ureteral stenosis (Mueller et al., 1995).

Cytomegalovirus (CMV) is the most common viral infection following kidney transplantation. Without prophylaxis, CMV disease occurred in 45% of recipients with high-risk CMV serostatus (donor CMV seropositive and recipient CMV seronegative) (Lowance et al., 1999). CMV infection has been associated with reduced renal allograft function and survival (Kliem et al., 2008; Helanterä et al., 2006). However, invasive CMV disease involving the renal allograft is apparently uncommon. This may be

attributed to the rarity of detecting CMV inclusion in renal allograft biopsies (<1%) despite the presence of concurrent renal dysfunction and CMV disease. The spectrum of renal allograft pathology caused by CMV can demonstrate tubulointerstitial changes or glomerular involvement. Tubulointerstitial nephritis caused by CMV is the more common manifestation in renal allograft. CMV glomerulopathy, which can occur with or without concomitant tubulointerstitial disease, has been reported (Rane et al., 2012). A case of CMV-induced necrotizing and crescentic glomerulonephritis in renal transplant patient has been described (Detwiler et al., 1998).

Diagnosis

CMV can be detected by seroconversion in a previously negative host and increase in IgM and IgG antibodies titers (Kalil et al., 2005), but a high prevalence of latent CMV infection makes serologic diagnosis difficult, and detection of CMV antigen (pp65), RNA, or DNA is commonly used. The pp65 antigenemia and real-time PCR have been compared with each other, and real-time PCR seems to correlate better with the clinical picture (Mengoli et al., 2004).

Treatment

Letermovir has been shown in a placebo-controlled randomized trial to decrease the risk for clinically significant CMV infection (need for preemptive antiviral therapy and/or CMV disease) and also decrease all cause mortality in CMV (+) patients. Most patients receive prophylaxis with ganciclovir after solid organ transplantation; however, in active diseases, other drugs, such as foscarnet, 60 mg/kg IV twice daily for 14 days, can be used because they are active against CMV (Bielorai et al., 2001). Ganciclovir can reduce the risk for CMV disease but is associated with significant toxicity. High-dose acyclovir/valaciclovir can reduce the risk for CMV replication. The data regarding prophylactic Ig is conflicting and its use is currently not recommended.

Ganciclovir (valganciclovir) and foscarnet are the most used drugs for CMV disease. The addition of high-dose Ig for treatment of CMV pneumonia has been commonly used, but the data supporting this combination is limited. There is no data supporting the addition of Ig to antiviral treatment for other types of CMV disease. Cidofovir is also a possibility for second- or third-line antiviral therapy (Ljungman et al., 2019), whose duration has to be decided on a case-by-case basis, but normally longer therapy is needed compared to preemptive therapy (6–8 weeks). Cidofovir is active against both BKV and CMV and has been used if both viruses are detected. For this reason, cidofovir may become a drug of choice in patients who present with hemorrhagic cystitis after solid organ or bone marrow transplantation. New antiviral drugs are in development but have not been proven efficacious on this indication. Leflunomide and artesunate have been tested, but data supporting their use is very limited.

Several groups have tried to prevent or treat CMV infection and disease following allo-HSCT by the transfer of CMV-specific T-cells. The transfer of these cells was shown to reconstitute virus-specific T-cell immunity. When given therapeutically to patients with chemotherapy-refractory CMV infection, a drop in the viral load after an increase in the number of CMV-specific T-cells could be documented. In patients with chemotherapy-refractory CMV infection postHSCT, adoptive T-cell therapy is a valid therapeutic option (Ljungman et al., 2019).

Human papilloma virus

Recently, human papillomavirus (HPV) has been suggested as a causative agent for squamous cell carcinoma (SCC) of the urinary bladder (Kim et al., 2014). Whether HPV also plays a significant role as etiological factor in other urinary cancers is less clear.

HPV is a double-stranded circular DNA virus of approximately 8000 base pairs, containing eight genes; E1, E2, E4, E5, E6, E7, L1, and L2 (Narisawa-Saito and Kiyono, 2007). The L1 gene encodes the principal capsid protein. Today, approximately 120 different genotypes are known. To be classified as a genotype the sequence of the L1 region has to be >10% different from the L1 region in any other HPV genome. The most common types, among women with HPV DNA positive cervical uterine cancer, are in descending order of frequency, HPV 16, 18, 45, 31, 33, 52, 58, and 35. Furthermore, HPV can be classified into low risk (LR), probable high risk (pHR), and high risk (HR) HPV types according to their prevalence in benign and malignant lesions where causality has been established (Munoz et al., 2003). The tumor suppressor p16INK4a (p16) is well known to be associated with HR HPV infection in cervical uterine cancer and oropharyngeal cancer, which is why it has been suggested as a surrogate marker for HPV infection in bladder cancer.

HPV is a common sexually transmitted infection among women and men, with a life-time risk of infection of approximately 80% for sexually active women. The virus is linked to almost 10% of cancers worldwide, especially a subset of squamous cell carcinoma of the cervix uteri, vulva, penis, anus, and oropharynx. It is therefore anticipated that the virus has affinity for squamous cells. In as much as 90% of cases, the HPV infection is cleared spontaneously by an effective cell-mediated immune response. HPV evades the innate immune system, delaying activation of the adaptive immune system which is the agent responsible for removal of the HPV infection. The remaining 10% with a persistent infection thus have increased hazard of oncogenic progression in case of an HR HPV infection (Stanley, 2010).

A geographical variety in HPV prevalence exists. The HPV prevalence has been presented to be highest in Asia. Compared with this, a significantly lower prevalence was demonstrated in Europe. Genetic difference, differences in environmental risk factors (including sexual behavior) and other unknown sources may explain such geographical variety. Comparing studies from different regions of the world should be taken into consideration such geographical variety (Li et al., 2011).

Studies investigating the simultaneous presence of HPV DNA and p16 overexpression have shown as high as 94% incidence in bladder cancer and 8.8% in other urinary with squamous cell differentiation. In the latter study on 35 cases with a HPV prevalence of 17.1%, a high p16 overexpression of 45.7% was demonstrated (Kim et al., 2014). A meta-analysis including 37 studies with 2246 cases of bladder cancer focused on the topic of an association between p16 and prognosis or clinicopathology in bladder cancer cases. The meta-analysis showed a downregulation of p16 in bladder cancer (Gan et al., 2016). Consequently, the knowledge on the association of BC, HPV, and p16 is even more uncertain than the association between HPV and bladder cancer.

Association between HPV presence and positive p16 staining seems to be equally unclear and, therefore, negative p16 staining cannot rule out HPV infection in bladder cancer tissue. Although HPV infection has been found in bladder cancer studies, it is important to keep in mind that such an association is not equivalent to causation. Thus, clear etiological association between HPV and bladder cancer development cannot be established at this point.

Viral-induced glomerulonephritis

Viruses are capable of inducing a wide spectrum of glomerular disorders with variable immune response and different histologic forms of glomerular injury. Although emerging data emphasizes the role of occult viral disease in the development of glomerulonephritis (GN), the criteria to define a viral illness should include: the demonstration of active viremia primarily through serologic PCR testing, the identification of viral proteins/nucleic acid residues within renal tissue and/or within immune complexes deposited in the glomerular basement membrane, and the regression of the glomerular lesion concomitant with the host immune clearance of viremia or eradication of viremia through antiviral therapy. The present classification is based on the duration of active viremia, chronic or acute/subacute.

Glomerular syndromes associated with long-term chronic infections

HCV

Similar to HBV, HCV-associated glomerular disease is primarily a consequence of viral antigen – immune complex formation with glomerular basement membrane deposition. The histologic aspect include type 1 membranoproliferative glomerulonephritis (MPGN) as a consequence of type 2 mixed cryoglobulinemia, polyarteritis nodosa from immune complex deposition, mesangial proliferative and focal proliferative GN and IgA nephropathy. It is important to note that most renal diseases in HCV patients with liver disease are a consequence of acute tubular necrosis, hepatorenal syndrome, prerenal azotemia, chronic kidney disease, and not GN. Therefore, it is essential to be aware of the characteristics of acute GN in HCV patients, differentiating them from the more common diagnoses causing acute kidney insufficiency in this population (Kupin, 2017a, b). Oral direct-acting antivirals (DAAs) against HCV replaced Interferon and became the mainstay of treatment, providing long-term successful eradication of HCV and elimination of cryoglobulinemia. A variety of drugs in this class have been developed that are used in combination over a 12-week period without Interferon and result in sustained viral remissions of 95% (Sise). It has also been proved that persistent HCV infection was independently associated with chronic kidney disease, and that antiviral treatment with IFN plus ribavirin can improve renal function and reverse chronic kidney disease (Zhang et al., 2019).

HIV

The HIV pandemic involves 37 million active carriers in the world, significantly less than the 240 million carriers of HBV and the 170 million carriers of HCV. The differential diagnosis of glomerular disease in this setting will be influenced by the treatment status in relation to combined Antiretroviral Therapy (cART-naïve versus actively on cART), and by their coinfection status with HBV (5–10%) or with HCV (25–30%). As with HCV, the prerequisite need for ongoing active viremia is essential for the development of HIV-related glomerular syndromes: HIV-associated nephropathy (HIVAN) and HIV immune complex disease of the kidney (HIVICK) (Sise et al., 2016).

HIVAN embraces glomerular injury arising from direct viral infection, particularly the visceral and parietal epithelial cells, without the presence of immune complexes. The lifetime risk of HIVAN in an untreated HIV-infected black patient is 2–10%, rising to 50% in homozygous for the APOL1 variants (Kruzel-Davila et al., 2016). It should be considered in any cART-naïve HIV patient of black race ancestry with any degree of abnormal albuminuria or proteinuria. New emerging therapy for HIVAN includes renin-angiotensin-aldosterone system inhibition, interruption of the mTOR pathway, and retinoic acid derivatives (Kumar et al., 2010).

Unlike HIVAN, HIVICK includes a constellation of histopathologic diseases with a different presentation and prognosis (Booth et al., 2016). It derives from the deposition of immune complexes in the glomerulus and it is a complication of active HIV viremia in a cART-naïve patient or a patient with cART resistance. Like HIVAN, HIVICK glomerular lesions from coinfecting HIV patients with HBV or HCV are not considered HIVICK and are classified separately as secondary lesions due to their individual viruses. Because 50% of the lesions are postinfectious, these would not be expected to improve with cART, whereas the remaining immune complex glomerular diseases should theoretically show benefit depending on their degree of chronicity. However, the heterogeneity of HIVICK and the limited number of studies makes it difficult to make a recommendation on the benefit of cART (Foy et al., 2013).

HBV

Overall, renal disease may occur in 3–5% of patients with chronic HBV infection (Gupta and Quigg, 2015). Immune-complex GN (MPGN and IgA nephropathy) or immune complex–related vasculitis (polyarteritis nodosa) are the histologic manifestations of HBV-associated renal disease. Of note, many patients with chronic HBV may also harbor coexistent HIV (5–10%) and HCV (10–30%). Checking for these viruses in all HBV carriers is essential (Basnayake and Easterbrook, 2016). Antiviral agents and corticosteroids are mainstay of treatment. The Kidney Disease Improving Global Outcomes recommends the use of IFN or oral antiviral agents (tenofovir, adefovir) or nucleoside (lamivudine, entecavir, telbivudine) reverse transcription inhibitors (KDIGO, 2012). Corticosteroids may be given for a period of <6 months without a significant effect on liver disease, HBV viremia, or patient morbidity or mortality as long as concomitant antiviral therapy is used (Zheng et al., 2012). Universal HBV vaccination reduced those childhood cases of HBV membranoproliferative related to horizontal transmission of the virus (Liao et al., 2011).

Glomerular syndromes associated with acute/subacute viral infections

This focus is on individual types of glomerular lesions seen with a variety of acute and subacute viral infections including cytomegalovirus (CMV), parvovirus, Epstein–Barr virus (EBV), hantavirus, and dengue. An accurate differential diagnosis in case of GN should rule out acute or chronic viral infections. Familiarity with the main renal syndromes associated with viral diseases is essential in order to begin accurate testing and therapeutic interventions (Kupin, 2017a, b).

Although any acute viral illness can lead to an immune complex–proliferative glomerulonephritis (GN), a select group of viral syndromes can induce glomerular injury: dengue, hantavirus, and non-HIV viruses associated with collapsing FSGS (cFSGS) (parvovirus, EBV, and cytomegalovirus).

Dengue

Dengue is a worldwide infection with estimated 100 million new per year. It is classified into dengue fever, dengue hemorrhagic fever, and dengue shock syndrome. GN in dengue results not only from immune complex deposition but also from direct viral entry into renal tissue (Lizarraga and Nayer, 2014). Treatment remains supportive in all categories of dengue.

Hantavirus

Hantaviruses are RNA viruses of the *Bunyaviridae* family which are associated with two major syndromes: hanta pulmonary syndrome and hemorrhagic fever with renal syndrome, characterized by diffuse endothelial cell injury as a consequence of direct viral infection. Similar to dengue, no specific therapy is available for hantavirus infection but preventive strategies with widespread vaccination are undergoing clinical trials (Kruger et al., 2015).

Collapsing focal segmental glomerulosclerosis

Viral-induced Collapsing Focal Segmental Glomerulosclerosis (cFSGS) has long been associated with parvovirus B19, CMV, and EBV. These viruses can cause acute immune complex GN especially with vertical transmission and membranous glomerulopathy has been the most common renal histology reported in this setting. In addition, CMV causes a distinct tubulointerstitial nephritis in transplant patients and may play a role in the development of transplant glomerulopathy (Beneck et al., 1986).

Covid-19 and urinary tract involvement

The current pandemic has seen a new character arising from the multitude of human viral pathogens. SARS-CoV-2 has been shown to be a global player, potentially involving any anatomic site or function. Although the abundance of the virus genetic material in both urine (ca. 10^2 – 10^5 gc/mL) and feces (ca. 10^2 – 10^7 gc/mL) is much lower than in nasopharyngeal fluids (ca. 10^5 – 10^{11} gc/mL) (Jones), it is believed that urinary symptoms are caused by a direct action of SARS-CoV-2. Urinary frequency has been identified as an additional symptom of SARS-CoV-2 infection independent of acute renal injury or urinary tract infection in a small series of hospitalized patients (Mumm et al., 2020). It has been also suggested that the urinary tract may become the target of life-threatening involvement by SARS-CoV-2, especially in patients with pre-existing urologic conditions (Luciani et al., 2020). This assumption is based on the finding that the bladder urothelium, as well as the kidney, harbors cells expressing ACE2, the receptor for the viral spike protein (Zou et al., 2020; Sise et al., 2020). In the face of a possible prolonged or recurring waves of the pandemic, clinicians should be aware that a nontypical course of hematuria or other urinary symptoms might be related to a COVID-19 infection. Although the likelihood of infection due to contact with sewage-contaminated water is low, it has also been speculated that a risk of transmission might occur in clinical and care home settings where secondary handling of people and urine/fecal matter occurs (Jones et al., 2020).

Glossary

Balanitis Infection of the penis head.

Candiduria Defined as the detection of ≥ 1000 CFU/mL of yeast from at least 2 urine cultures; urinary symptoms can be present (symptomatic) or absent (asymptomatic).

Community-associated UTI (CAUTI) UTI that is acquired outside hospital setting or at least the patient is not admitted in the hospital for more than 48 h.

Complicated UTI UTIs that are complicated by several risk factors that can result to treatment failure, recurrence of infection, significant morbidity and even mortality.

Cystitis Bladder inflammation, usually as a result of infection.

Dysuria Pain or discomfort when urinating.

Healthcare-associated UTI (HAUTI) UTIs acquired from the hospitals (nosocomial).

Hematogenous Distributed or spread via the bloodstream.

Lower UTI UTI localized to the lower urinary tract (bladder, prostate and urethra).

Non-*albicans* *Candida* species (NACS) Clinically-relevant *Candida* spp. that is not *Candida albicans*.

Perianal Area around the anus.

Prostatitis Infection of the prostate that may present symptoms such as pain in the groin, painful and difficulty urinating.

Pyelonephritis Inflammation of the kidney arising as a result of infection often accompanied by fever.

Uncomplicated UTI UTIs where there are no relevant functional or anatomical abnormalities presented and no relevant concomitant diseases promoting the UTI. The risk of uncomplicated UTI developing serious complication is low.

Upper UTI UTI localized to the upper urinary tract (kidney).

Urethritis Inflammation and irritation of the urethra, usually due to infection.

Urinary Tract Infection (UTI) Infection of the urinary tract, which can be either upper or lower UTI, uncomplicated or complicated.

Urogenital Refers to both urinary and genital organs.

Vulvovaginal candidiasis (VVC) *Candida* infection localized to the vulvovaginal area of the female reproductive organ.

Introduction

Urinary tract infections (UTIs) are among the most common microbial infections in humans with an annual worldwide prevalence of approximately 150 million people affected and an estimated lifetime incidence of 50–60% among women (Medina and Castillo-Pino, 2019). Worldwide, there were roughly 8.3 million office visits and more than 1 million hospitalizations to treat UTIs with an overall associated annual cost >\$1 billion. The prevalence of UTIs increases with age though they remain a significant cause of morbidity in different human population groups ranging from neonates/infants, older men, and women of all ages. In a European prevalence survey from 2016 to 2017, UTIs accounted for 18.9% of healthcare associated infections (HAI) in acute care hospitals (ACH) and 32% in long term care facilities (LTCF) (Suetens et al., 2018). Although most infections were of bacterial etiology, fungal-related UTIs represented a significant proportion of the total UTI cases (Medina and Castillo-Pino, 2019).

Among the fungal species frequently isolated, *Candida* spp. remain the most important. *Candida* spp. represent the fourth leading cause of hospital-acquired infections in the US and account for about 8–10% of all nosocomial blood stream infections (Wisplinghoff et al., 2004; reviewed in Pfaller and Diekema, 2007). The overall mortality of systemic *Candida* spp. infections can be as high as 40% (reviewed in Kullberg and Arendrup, 2015). The increasing trend of fungal infection has been attributed to the widespread use of broad-spectrum antibiotics and immunosuppressive drugs like corticosteroids, the increase in the number of HIV and AIDS patients, the application of immunosuppressing medical procedures such as chemotherapy, and the alarming epidemics of obesity and diabetes (reviewed in Pfaller and Diekema, 2007; Kullberg and Arendrup, 2015; Bongomin et al., 2017). Although the majority of the reports regarding fungal UTIs are focused on *C. albicans*, the most important representative species of the *Candida* group, the contribution of other *Candida* species collectively known as Non-*albicans Candida* Species (NACS), which include *C. glabrata*, *C. tropicalis*, *C. krusei*, *C. parapsilosis*, and *C. auris* to UTI pathogenesis is not well understood despite the increasing incidence of NACS-related genitourinary tract infections (Dorko et al., 2002; Powell et al., 2016; Mekanjuola et al., 2018; Biagi et al., 2019; Jabeen et al., 2020). Compared to *C. albicans* and *C. glabrata*, literature describing the fundamental biology of NACS is limited and currently an area of active investigation (Butler et al., 2009; Lackey et al., 2013; Deorukhkar et al., 2014; Feistel et al., 2019; Du et al., 2020).

Candida spp. exist as natural commensals and routinely colonize mucosal surfaces, the external genitalia, and urethral meatus even of healthy premenopausal women (Sobel, 2011). *Candida* spp. have been found in 1% of “clean” voided urine specimens in a healthy population, 5% of all urine cultures in the hospital setting, and 10% of urine isolates in a tertiary care facilities (Nayman Alpat et al., 2011; Rivett et al., 1986). Recently, *C. auris*, first identified in Japan in 2009 from an external ear canal discharge from a female patient, has received global recognition as an emerging and serious global health threat, especially in nosocomial settings, due to their highly invasive nature and multidrug resistance properties (Biagi et al., 2019; Du et al., 2020; Lockhart et al., 2017; Iguchi et al., 2019). It should be noted that other fungal species such as *Cryptococcus neoformans* (Poloni et al., 2013), *Aspergillus* spp. (Flechner and McAninch, 1981; Rao, 2015; Shirwany et al., 1998; Hadaya et al., 1998; Zhou et al., 2017), *Rhizopus* spp. (Barnes et al., 2017), *Mucor* spp. (Perez de la Espejo et al., 2004; Mathew et al., 2019), *Trichosporon asahii* (Sood et al., 2006; Kumar et al., 2011; Sun et al., 2012; Khan et al., 2015; Iken et al., 2015; Urs et al., 2018) and *Blastomyces* spp. (Vahidi et al., 2018) have been found in very rare instances of UTIs.

UTIs can be categorized according to the region of the urinary tract affected; they can either be upper or lower urinary tract infections, which can be presented with or without symptoms. Upper UTIs involve the kidney (pyelonephritis), whereas lower UTIs involve the bladder (cystitis), urethra (urethritis), and prostate (prostatitis) in men (Najar et al., 2009) (Fig. 1). In actual clinical practice, differentiating between these two regions is often difficult as infection often spreads from one area to the other. In most cases, the term UTI is used to describe pyelonephritis and cystitis, although urethritis and prostatitis are infections that also involve the urinary tract. UTIs can occur as a result of ascending or through hematogenous spread. In ascending UTIs, the infection originates in the lower urinary tract; for example, the vulvar region (urethral region included) in women, which may be periodically colonized by *Candida* spp. originating from the rectum as a result of migration across the perianal area (Nayman Alpat et al., 2011; Tomczak et al., 2014). Usually, ascending UTI occur in patients with in-dwelling catheters where *Candida* can form biofilms, facilitating their persistence for extended times. These organisms can ascend to the bladder or in rare cases, to the kidney, causing infection in all of these regions. Of grave concern is once *Candida* spp. have infected the kidneys, the infection can spread to neighboring tissues or to distant regions via the bloodstream (candidemia). Most observational studies have found that candiduria (presence of yeast cells in urine) in asymptomatic patients does not commonly lead to candidemia (1.3–8%), and in cases where candiduria progressed to candidemia, a urinary tract obstruction was found, the consequence of a urinary tract procedure (Kauffman et al., 2000; Bougnoux et al., 2008; Ang et al., 1993). *C. albicans* prostatitis occurs infrequently in patients with diabetes. In hematogenous routes, renal (kidney) infection can occur as a result of dissemination from the blood, likely during invasive candidiasis. Other complications of *Candida* infection include the appearance of fungus balls in the renal pelvis, ureter, or bladder that can lead to obstruction in these areas. Papillary necrosis and intra-renal and perinephric abscesses may form resulting in reduced kidney function.

Less common, the sources of the infection have been traced to sexual activity, originating from an infected asymptomatic partner carrying *Candida*. In males, the penile foreskin can harbor *Candida*, which can be a source of infection during intercourse (Lisboa et al., 2010a,b; Wray et al., 2020). Although they share some general overlapping symptoms and affect the urogenital tract and may predispose the infected individuals to UTI development when left untreated, it is important to note that the common yeast infection affecting the genitals of women (vulvovaginal candidiasis; VVC) and men (candida balanitis; CB) are distinct types of infection.

Candida spp. as a major etiological agent of UTI in humans

Candida spp. belong to the phylum *Ascomycota*, subphylum *Saccharomycotina*, which includes a great variety of human pathogenic fungi. Most pathogenic yeasts that include *C. albicans* and *C. tropicalis* belong to the CTG clade where they decode CUG (CTG) codons as serine instead of leucine. The second main group of pathogenic yeasts such as *C. glabrata* belong to the Nakaseomyces clade, one of the so-called post-WGD (post whole genome duplication) lineages where the genomes of member species have undergone a complete duplication and is largely represented by the non-pathogenic brewer's yeast, *Saccharomyces cerevisiae* (Gabaldon et al., 2016). The non-canonical codon usage of *C. albicans*, as of all CTG-clade species, represents one of the major challenges that has hampered genetic studies of these *Candida* species. As already mentioned, of the *Candida* spp., *C. albicans* is the most frequent etiology of fungal infection in humans. *C. albicans* are integral part of our natural microbiome and can be found inhabiting the skin and mucosal surfaces, and is detectable in the majority of healthy individuals. On standard yeast-peptone-dextrose (YPD) or Sabouraud Dextrose (SD) nutrient plate, *C. albicans* (and other *Candida* spp.) form white- to cream-colored colonies (Fig. 2A, left). Differential medium, such as CHROM-Pal agar, can be used for the presumptive identification of *Candida* spp. from clinical samples (Fig. 2A, right) (Sahand et al., 2009).

C. albicans can exist in different cellular morphologies inside the human body, and hence it is known as a pleomorphic organism (Fig. 2B). Important are the three major morphologies: yeast, pseudohyphae, and true hyphae, where the latter two are classically known as filamentous morphologies (Sudbery, 2011; Berman, 2006). Morphological transitions, will be discussed in more detail later in this review. Yeast-like cells can exist in various morphotypes. In addition to the well-known white phenotype, yeast cells can become opaque, which are elongated cells characterized by "pimple"-containing structures on their cell surface. More recently, the GUT and Grey yeast morphotypes have been identified and have been implicated in both commensalism and virulence (Noble et al., 2017). In addition, in certain conditions like starvation, *C. albicans* can form a large distinct cellular structure at the terminal cells of mycelia known as the chlamydo-spore, the function of which is not fully understood (Noble et al., 2017; Gow, 2013).

C. albicans was among the first eukaryotic pathogens with a completely sequenced genome. Other *Candida* spp. that have important clinical significance such as *C. glabrata* and *C. tropicalis* have also been sequenced. *C. albicans* is a diploid (2N) yeast with a haploid genome size of around 16 MB distributed to 8 chromosomes (Chromosomes R and 1–7) (van het Hoog et al., 2007; Jones et al., 2004). The genome is highly polymorphic and exhibits considerable natural heterozygosity. *C. albicans* is a naturally occurring diploid organism that predominantly reproduces asexually by budding. Although long considered to be an obligate diploid, *C. albicans* can exist and tolerate discrete ploidy states, ranging from the haploid state to tetraploid; each state associated with distinct cellular properties (Noble et al., 2017; Ene and Bennett, 2014) (Fig. 2C). Like the closely related brewer's yeast, *Saccharomyces cerevisiae*, *C. albicans* possess a and α mating type alleles at a conserved mating type locus (MTL). Unlike *S. cerevisiae*, *C. albicans*

Fig. 2 (A) (Left) *Candida albicans* (SC5314 laboratory strain) colonies grown on YPD agar for 48 h at 30 °C. (Right) Colony color and morphologies of different *Candida* spp. growing on CH-Pal agar medium. Cal, *C. albicans*; Cdu, *C. dubliniensis*; Cgl, *C. glabrata*; Cgu, *C. guilliermondii*; Ckr, *C. krusei*; Cpa, *C. parapsilosis*; Ctr, *C. tropicalis*. (B) Pleomorphism in *C. albicans*. *C. albicans* can assume different morphologies ranging from the classical yeast (white) form to the filamentous pseudohyphal and hyphal forms. The yeast-like form can exist in distinct morphotypes such as the opaque, GUT, and grey phenotypes. In addition, *C. albicans* can form large spherical suspensor structures at the end of hyphal tips known as chlamydospores. Most of these forms (e.g., yeast and hypha) have been implicated in virulence whereas the functions of the other forms are relatively less understood and are actively investigated. (C) Parasexual cycle of *C. albicans*. Parasexual cycle in *C. albicans* involves the Mating Type-Like Locus (*MTL*) that is similar to *S. cerevisiae* *MAT* locus. The *MTL* locus is naturally heterozygous ($MTLa/MTL\alpha$) (Ene and Bennett, 2014; Bennett, 2015). However, under certain conditions such as growth on Sorbose, one of the *MTL* alleles is eliminated due to the loss of one chromosome 5, resulting in an aneuploid diploid cell that possesses only *MTLa* or *MTL\alpha* allele (Noble and Johnson, 2007). An epigenetic change can facilitate the phenotypic switching from the white (a/a or α/α) to the opaque phenotype (a/a or α/α). Opaque cells are mating-competent and can mate forming a tetraploid ($a/a/\alpha/\alpha$), which subsequently revert to the diploid state, and sometimes to aneuploid progeny, through concerted chromosome loss (Noble and Johnson, 2007). (A) Image adapted from Sahand IH, et al. (2009) Evaluation of CHROM-pal medium for the isolation and direct identification of *Candida dubliniensis* in primary cultures from the oral cavity. *Journal of Medical Microbiology* 58(Pt 11): 1437–1442.

appears unable to undergo meiosis (Ene and Bennett, 2014; Bennett, 2015). However, under conditions of stress, either chromosome loss or rare gene conversion events at the *MTL* result in a or α aneuploid, or a/a or α/α diploid strains, respectively, that can mate in a parasexual manner. This involves the formation of unstable tetraploid (4N) progeny that then revert to the diploid state via concerted chromosome loss (Noble and Johnson, 2007).

Candida albicans pathogenicity mechanisms

As a human commensal, *C. albicans* can asymptotically colonize virtually all anatomical sites in the body, including the skin, the oral and oropharyngeal cavities, the gastrointestinal and urogenital tracts, each serving as discrete niches (Kullberg and Arendrup, 2015; Moyes and Naglik, 2011). Relative to other sites, the vagina represents an entirely distinct microenvironment in terms of nutritional composition, competing microbiota, local environmental stress, and presence and rigor of innate immune defenses (Brown et al., 2014). Clearly, *C. albicans* needs to properly adapt to this environment to ensure successful colonization, and later on establish infection (Brown et al., 2014). The capacity of *C. albicans* to successfully infect a niche is attributed to a large set of virulence factors that include the expression of adhesins facilitating adhesion to host cells, biofilm formation, secretion of hydrolytic enzymes and cytolytic peptides (i.e., Candidalysin), morphological switching between the yeast and filamentous forms, and phenotypic switching (Fig. 3). Recently, other fitness attributes, including tolerance to host-imposed stress, efficient nutrient acquisition systems, and the presence of robust and flexible metabolic machinery, are now considered contributing factors to *C. albicans* pathogenicity (Brown et al., 2014; Mayer et al., 2013; Malavia et al., 2017). Interestingly, some of these attributes are also linked to the pathogenicity of other clinically-relevant *Candida* spp. such as the filamentous growth (*C. tropicalis* and *C. dubliniensis*), adhesion to epithelial surfaces (*C. glabrata*), phenotypic switching (*C. tropicalis*), tolerance to host-imposed stress (*C. glabrata*), and metabolic flexibility (*C. glabrata*).

Adhesion and invasion

Adherence to host tissues is often considered as an essential early step in the colonization of different niches. A critical step during colonization of the urinary tract is the ability of *C. albicans* to adhere to epithelial cells in the vagina, urethra, bladder, or even kidney (Lentz, 2009). Adherence to host cells is primarily attributed to cell surface glycoproteins encoded by the *ALS* (agglutinin-like sequence) and *HWP1* genes acting as multi-functional adhesive molecules (Hoyer, 2001). The *C. albicans* *ALS* gene family consists of eight genes, *ALS1*–*ALS7* and *ALS9* (Hoyer, 2001), one of them (i.e., *ALS3*) is known to encode for a glycoprotein that is also a downstream effector of hyphal growth that facilitates adhesion and flocculation of *C. albicans*. Another well-characterized adhesin in *C. albicans* is Hwp1, a hyphae-specific cell surface protein, initially synthesized as a glycosyl-phosphatidylinositol (GPI) anchored protein that eventually becomes covalently cross-linked to $\beta(1,3)$ -glucan via $\beta(1,6)$ -glucan in the cell wall (Staab et al., 2004). Hwp1 mediates tight adherence to epithelial cells by a mechanism that requires the participation of a specific host cell surface protein. The N-terminal domain of Hwp1 serves as a substrate for mammalian transglutaminases that crosslink this protein to the protein present in the host cell surface (Staab et al., 2004). Null mutations in *HWP1* (*hwp1* Δ/Δ) impair the capacity of *C. albicans* to adhere to oral epithelial cells and display reduced virulence in a murine systemic infection model (Staab et al., 1999). In *C. glabrata*, the process of tissue adherence is associated with glycoproteins encoded by the *EPA* (epithelial adhesion) genes.

Fig. 3 Virulence factors of *Candida albicans*. *C. albicans* can show a plethora of virulence factors that enables it to colonize and later on establish infection in a certain host niche. Virulence factors that are linked to *C. albicans* pathogenicity include the capacity to undergo morphological (yeast to hypha) switching, adhere and invade host cells, secrete hydrolytic enzymes to degrade host tissues, secrete a cytolytic toxin (candidalysin), form complex biofilms, assimilate trace nutrients (e.g., trace metals) that are actively withheld by the host (known as nutritional immunity), escape or persist in the phagosome of innate immune cells such as macrophages, phenotypic switching which enables mating, and the presence of a robust and flexible metabolic machinery.

Morphological switching

In response to a large repertoire of environmental cues, *C. albicans* cells can reversibly switch between yeast and filamentous (hyphae and pseudohyphae) morphologies (Fig. 4A). Well-studied inducers of morphogenesis reflecting the diversity of microenvironments within the host include serum, CO₂, certain nutrients (e.g., glucose, amino acids, *N*-acetylglucosamine), temperature, and nitrogen starvation (Cottier and Muhlschlegel, 2009). Yeast forms are oval cells that asymmetrically divide into mother and daughter cells by axial or bipolar budding. Pseudohyphae and hyphae are two distinct morphologies that can easily be confused with each other, as pseudohyphae can sometimes superficially resemble true hyphae; both filamentous forms exhibit similar long elongated structures. However, these two forms are quite distinct. Hyphae, for example, initiate as germ tubes at a bud site, and assume polarized growth with elongated cells with completely parallel sides that lack constrictions at the sites of septation, whereas pseudohyphae are much wider and become clearly constricted at every septal junction (Fig. 4A; Sudbery, 2011). The yeast form is well-tolerated by the host and are maintained at low numbers on the vaginal epithelial surface by several mechanisms that also inhibit the transition to the filamentous form. In the laboratory, when this capacity to switch is genetically disabled in *C. albicans*, for example by inactivating transcription factors Efg1 and Cph1 that are important for transducing hyphal-inducing signals to target genes, *C. albicans* fail to mount infections as assayed in a number of in vitro and in vivo infection models. Cumulated results consistently support the concept that morphogenesis is an essential virulence attribute (Sudbery, 2011; Lo et al., 1997; Sudbery et al., 2004; Lorenz et al., 2004). Other *Candida* spp., such as *C. tropicalis* and *C. dubliniensis* are known to form true hyphae though they are considered less robust than *C. albicans*. *C. glabrata* does not form hyphae or pseudohyphae, even under conditions that trigger robust hyphal growth in *C. albicans* (Fig. 4B).

As will be discussed later in this review, the higher incidence of *Candida* UTI in women is linked to the vagina being an important reservoir for *C. albicans*. The vaginal environment is dynamic (Fig. 5). The vaginal epithelium together with associated physiological secretions (vaginal fluid/cervical mucus) and resident commensal bacterial microflora contribute to maintaining an acidic environment that represses filamentation of *C. albicans* (Boskey et al., 1999; Gorodeski et al., 2005). However, the vaginal epithelium (matrix) represents an inherently conducive environment for morphological switching of fungal cells. Particularly, the physical contact to epithelial surfaces, the constant temperature of 37 °C and elevated levels of CO₂ are established factors that favor filamentous growth (Biswas et al., 2007). In sexually mature women the vaginal epithelium undergoes transient changes that can induce filamentation. The pH of cervical mucus is usually acidic (pH of 4–4.5; non-inducing), however during menses it increases to pH 6.8 (inducing). The introduction of seminal fluid, which is alkaline (pH of 7–8.5), can transiently raise the pH within the vagina (Masters and Johnson, 1966). Serum present during menstruation and the deposition of seminal fluid during coitus introduces high concentrations of known morphogenic factors, including amino acids and proteins, and in the case of seminal fluid, *N*-acetylglucosamine (GlcNAc) (Alvarez et al., 2015). Morphological transition to hyphae enables *C. albicans* to strongly adhere to, then penetrate the mucosal layer and become intertwined with the vaginal epithelium resulting to hyperemia (increase in organ

Fig. 4 (A) *C. albicans* can exist in three main distinct morphological forms: the yeast, pseudohyphae, and true hyphae. Similar to diploid strains of the baker's yeast *Saccharomyces cerevisiae*, *C. albicans* can grow as ovoid yeast like-cells that can undergo morphological switching forming pseudohyphal cells, which have an elongated form, initiated by asymmetrical budding. *C. albicans* can also form true hyphae, which are similar to hyphae observed in other filamentous fungi that grow by continuous polarized growth and involves significant changes in cell cycle processes. Each of these forms can interconvert to one another, with the yeast-to-hyphal transition being the most well-characterized; (B) *C. albicans* constitutively expressing green fluorescent protein under the control of a strong *ADH1* gene promoter and *C. glabrata* constitutively expressing red fluorescent protein under the control of the *TDH3* gene promoter were grown together in cell culture medium (Dulbecco's Modified Eagle Medium, DMEM) supplemented with 10% fetal bovine serum for 2 h at 37 °C and 5% CO₂. Under these conditions, *C. albicans* switched to filamentous growth whereas *C. glabrata* remain in the yeast form (Silao and Ljungdahl, unpublished data). Scale bar = 10 µm.

Fig. 5 The vulvovaginal environment is dynamic. With respect to the development of VVC, it is important to differentiate between conductive, repressive and inducing environmental signals. There are relatively constant environmental factors, including the vaginal epithelium (matrix), temperature (37 °C), CO₂ levels, and bacterial microflora. In addition to the monthly hormonal cycle, there are transient fluctuations due to the introduction of body fluids, including serum and seminal fluid (SF). The matrix, 37 °C and CO₂ levels are inherently conductive, whereas the bacterial microflora contributes to repress morphological switching. Serum and SF induce morphological switching due to their elevated pH and to the high content of amino acids and protein in serum and semen, and GlcNAc in semen.

blood flow). When filamentous cells detach together with the recruited inflammatory cells from the invaded epithelial layers, debris from lysed cells and vaginal fluid come off as the characteristic cottage cheese-like vaginal discharge, which is one of the clinical signs and symptoms typical of VVC (Lobo et al., 2017; Cassone, 2015).

Biofilm formation

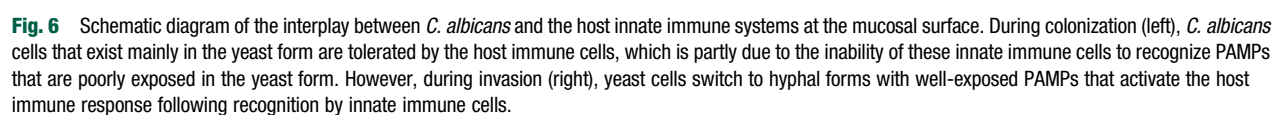

A consequence of *Candida* spp. adherence to surfaces is that they readily contribute to the formation of biofilms. Biofilms are often comprised of communities of cells embedded on a secreted extracellular matrix associated with mucosal surfaces or non-biological surfaces, such as those of implanted medical devices. *Candida* spp. biofilms are of major medical concern as cells growing in biofilms remain shielded from antifungal treatments and commonly gain resistance. As cells sluff off or detach from biofilms, cells with enhanced virulence properties can more readily disseminate and colonize other tissues and organs of the body, resulting in difficult-to-treat systemic infections. *C. albicans* is the most common fungus isolated from medical devices (Kojic and Darouiche, 2004), and catheters are, after diabetes, a major predisposing factor for fungal UTIs (Gharanfoli et al., 2019).

C. albicans biofilms contain a mix of both round, yeast-like cells and filamentous cells, all embedded in an extracellular matrix. In vitro and in vivo studies have shown that *Candida* biofilms develop in a concerted way with four clear stages initiating with adherence to a surface and ending with the dispersion of planktonic cells. The progression through these stages is dependent on a highly complex interplay of more than 50 transcriptional regulators (Lohse et al., 2018). The adhesion between hyphal cells is a very important feature of biofilm maturation, as it is the secretion of the extracellular matrix, composed mostly of glycoproteins. This, together with cellular components from the host, gives stability to the biofilm and generates protection against the immune system and antifungal drugs characteristic of *Candida* biofilms (Lohse et al., 2018).

All mucosal surfaces of the human body have a complex microbiome with several species of bacteria living alongside *C. albicans*. Interactions between *Candida* and bacteria are often mediated by small quorum sensing molecules and secreted virulence factors that exert synergistic and/or antagonistic effects (reviewed in Nogueira et al., 2019) and that influence the ability of *Candida* cells to participate in the formation of biofilms. As an example, *Candida* cells are able to suppress the growth of *E. coli* cells, in what may constitute a protection against bacterial UTI infections (Hall and Noverr, 2017). In the female reproductive tract, *Lactobacillus* spp. reduce the adhesion of *Candida* cells to the epithelium and their formation of hyphae (Sobel, 2007). On the other hand, the presence of seminal fluid in the vaginal tract transiently induces *C. albicans* filamentation (Alvarez et al., 2015; Rolo et al., 2020). The presence of *Candida* in the female reproductive tract also increases in situations of bacterial dysbiosis (van de Wijgert et al., 2014). *Candida* biofilms protect their cells from recognition and damage by the human immune system. For instance, neutrophils fail to activate, macrophages are pierced by *Candida* hyphal cells, while the complement and antimicrobial peptides are blocked (reviewed in Lohse et al., 2018). On top of that, *Candida* cells within the biofilms are also resistant to most antifungal drugs, in part due to the upregulation of efflux pumps (Ramage et al., 2002), but also due to the presence of β -1,3 glucan polysaccharides in the extracellular matrix that act as both a binder and a barrier against drug penetration (Nett et al., 2007). Hence, to fight against *Candida* biofilms, novel substances are needed that can disrupt the architecture of biofilms with the intention to promote access of antifungal drugs.

Another group of important hydrolases are phospholipases that play an important role in host cell membrane damage and invasion. Currently, there are four phospholipases identified in *C. albicans*: phospholipases A, B, C, and D. Increased production of phospholipases is often linked to virulence in animal models. Phospholipases are found concentrated at the hyphal tips and do not appear to increase adherence of *C. albicans* to host cells but rather increase the penetration of *C. albicans* by damaging the lipid components of the membrane, permitting invasion to other sites (Ghannoum, 2000). Recently, a novel secretory cytolytic peptide, candidalysin, was discovered from *C. albicans* that induces damage to epithelial membranes causing activation of the epithelial immune response and killing of macrophages via NLRP3 inflammasome activation (Moyes et al., 2016; Naglik et al., 2019; Kasper et al., 2018). The secreted peptide fragment is derived from the Kex2-dependent proteolytic processing of the hyphal specific protein Ece1. Only the third peptide fragment of Ece1 (Ece1-III) is shown to induce epithelial damage.

The capacity of our immune system to discriminate between colonization and invasion is paramount to controlling disease progression. The interaction of *C. albicans* and host immune cells during colonization and invasion has been extensively reviewed (Gow, 2013; Gow et al., 2012; Erwig and Gow, 2016; da Silva Dantas et al., 2016; Netea et al., 2008, 2015; Netea and Marodi, 2010; Cheng et al., 2012; Lionakis and Netea, 2013; Camilli et al., 2020). As an overview, mucosal surfaces such as those in the female reproductive tract are often colonized by *C. albicans* that exist mainly in the yeast form. However, this does not induce epithelial cell damage eliciting an immune response from epithelial cells or from macrophages (MC) and dendritic cells (DC). In the yeast form

pathogen-associated molecular patterns (PAMPs) are hidden or less exposed, which limits recognition by innate immune cells responsible for inflammasome activation. When yeast cells switch to hyphae, *C. albicans* becomes invasive and induces damage on epithelial cells. The switch exposes hidden PAMPs, which activate an immune response via inflammasome activation in MC and DC. This process results to the release of the pro-inflammatory cytokine, IL-1 β , which then stimulates the release of IL-17 and IL-22 from mature T_H17 cells. IL-17 and IL-22 cytokines are both crucial to mucosal antifungal response; IL-17 activates neutrophils whereas IL-22 stimulates the release of defensins from epithelial cells.

Commensal microbial communities such as those of *Lactobacillus* spp. (yellow cells, Fig. 6), antagonize *C. albicans* colonization, either through competition for sites of adhesion on epithelial cells or through secretion of surfactants that decrease fungal binding. As can be deduced from these observations, the vaginal microflora is an important factor that influences the incidence of UTIs in women. Alterations in the vaginal microflora disrupting the normal balance of the commensal vaginal organisms, often leading to reduced levels of *Lactobacillus* spp., are known to be associated with enhanced fungal growth and the development of UTIs (Czaja et al., 2009; Beerepoot and Geerlings, 2016) and recurrent UTIs (Kirjavainen et al., 2009). This is supported by Hooton et al., who reported that only 50% of premenopausal women with recurrent UTI have H₂O₂-producing lactobacilli in their vagina (Hooton et al., 2005).

Clinical management of Candida UTI

Risk factors

Most common risk factors of candiduria include diabetes mellitus, prolonged hospitalization, ICU admission, use of broad-spectrum antibiotics, instrumentation used to examine the urinary tract, and indwelling urinary tract devices. Other risk factors identified in some reports include: extremes of age, female sex, bladder dysfunction, urinary stasis, nephrolithiasis, renal transplantation, concomitant bacteriuria, congenital abnormalities of the urinary tract, structural abnormalities of the urinary tract, and presence of obstructions (bladder stones) (reviewed in Achkar and Fries, 2010). Fungal-related UTIs are more often diagnosed in women than in men due to anatomical structure differences such as a shorter urethra and the close proximity of the vagina and anus (Tomczak et al., 2014; Behzadi et al., 2010). Approximately 27% of women have recurrent infections. The vagina is the key anatomical site in the pathogenesis of *Candida* UTI in women as it serves as a main reservoir for the infecting organism. In addition, different epidemiological studies have identified additional risk factors for the development of UTI in women such as active sexual activity, delayed post-coital voiding, use of diaphragm and spermicide, and even pregnancy. The act of sexual intercourse can physically displace the microbiota into the introitus and further into the urethra. Delayed post-coital voiding allows stasis and may cause the organism to proliferate. The use of diaphragm and spermicide disrupts the vaginal microbiota by killing the *Lactobacillus* spp. which balances vaginal pH. Antimicrobial use alters the vaginal flora and could be a risk factor for UTI (Lentz, 2009; Lobo et al., 2017).

Diagnosis

The definition of candiduria is often unclear. It may be defined as the presence of ≥ 1000 CFU/mL of *Candida* spp. in cultures (Jacobs et al., 2018) or microscopic visualization of *Candida* spp. in urine sediment samples (Poloni and Rotta, 2020). Since *Candida* spp. are integral components of the human microbiota, the presence of fungal cells in cultures of urine samples does not necessarily indicate candiduria. Yeast colonization, specifically the presence of *Candida* cells in the urinary tract, does not necessarily require treatment because *Candida* spp. is very often cultured in the urine (Tomczak et al., 2014; Lentz, 2009; Fisher et al., 2011a). In the study by Tomczak in Poland, as many as 71% positive urine cultures were from women and the most common isolates were *C. albicans* and *C. glabrata* (Tomczak et al., 2014). This may have been due to vaginal candidiasis and urine contamination. Thus, further investigation should be done requiring the urine test to be repeated in newly obtained, clean-voided urine specimens to rule out the possibility of contamination prior to initiating antifungal therapy in these cases (Tomczak et al., 2014). In cases when obtaining clean-voided urine samples is not possible due to medical conditions of the patient, clean specimens can be obtained using catheter. In direct microscopic examination, *Candida* spp. can be easily identified via visualization of yeast and/or pseudo(hyphal) morphologies without the need to utilize special staining procedures (Fig. 7A). However, other very rare fungal species causing UTI such as *Cryptococcus neoformans* also exist in yeast form but this can be differentiated with *Candida* spp. via the presence of an encapsulating structure made up of polysaccharides around the yeast cell that can be readily observed using special stains such as India (or China) ink or mucicarmine and in some cases, even in unstained fresh urine samples (Fig. 7B) (Poloni et al., 2013; Poloni and Rotta, 2020).

Antifungal drugs

Commercially available antimycotic drugs used for treating patients include fluconazole, amphotericin B, caspofungin and/or flucytosine that can be topically, orally, or intravenously administered. Fluconazole belongs to the azole family, the largest group of antimycotic drugs that contains imidazole- and triazole-containing compounds (Fig. 8) (Mast et al., 2013). Azoles specifically inhibit the activity of the cytochrome P450 enzyme, lanosterol 14- β -demethylase (i.e., Erg11 or CYP51A1), required for ergosterol biosynthesis, which compromises the integrity of fungal cell membrane. Fluconazole is often the drug of choice for *Candida* UTI due

Fig. 7 (A) *C. albicans* identified in unstained urine sediments. (B) *Cryptococcus* spp. identified in a urinary cast. Images were adopted from Poloni JAT and Rotta LN (2020) Urine sediment findings and the immune response to pathologies in fungal urinary tract infections caused by *Candida* spp. *Journal of Fungi* 6(4): 245.

Fig. 8 Molecular structures of three generations of marketed (black) and experimental (gray) azole compounds developed to treat human mycoses. Azoles contain a five-membered heterocyclic ring containing a nitrogen atom and at least one other non-carbon atom, which can be nitrogen, sulfur, or oxygen. The numbering of heteroatom in clotrimazole, posaconazole, and voriconazole were indicated. Image was reprinted with permission Mast N, et al. (2013) Antifungal azoles: Structural insights into undesired tight binding to cholesterol-metabolizing CYP46A1. *Molecular Pharmacology* 84(1): 86–94.

to its safety profile and the ability to achieve a high urinary tract concentration. Other azole antifungals have minimal excretion of active compounds in the urine and are not useful for *Candida* UTI (Felton et al., 2014). Amphotericin B, another antifungal drug, is a polyene fungicidal agent that directly binds to cell membrane ergosterol forming transmembrane pores that facilitate the leakage of monovalent ions thereby disturbing cell membrane electrochemical potential. Amphotericin B (deoxycholate; AmB-d) is active

against most *Candida* species and are often used when fluconazole-resistant isolates are recovered from patients. Though effective, AmB-d is known for its renal toxicity. It has a lipid formulation (AmB-lip) designed to decrease renal toxicity; however, unlike its deoxycholate form (AmB-d) that can be excreted in high concentration in urine, AmB-lip does not achieve adequate levels in urine and kidney (Felton et al., 2014). When fluconazole-resistant *Candida* spp. are isolated from candiduria patients, the administration of AmB-d (with or without flucytosine) is necessary for all high-risk patients with or without symptom presentation. In pregnant women, Amphotericin B remains to be the drug of choice for the treatment of systemic fungal infections. Caspofungin belongs to echinocandin drugs, which is a new class of antifungal drugs that target fungal cell wall biosynthesis through inhibition of the enzyme β -1,3-glucan synthase. Other members of this class are micafungin and anidulafungin that can be also used as alternative antifungal therapy. Echinocandins, in general, have low concentrations (i.e., <2% of the dose) of active drug in urine and they are generally ineffective in treating *Candida* UTI (Kane and Muzevich, 2016; Sobel et al., 2007). However, there are case reports of successful treatment if the *Candida* infection is localized in the kidney and the infection is due to hematogenous spreading (Felton et al., 2014). Flucytosine (5-FC) is a synthetic nucleoside analog that exhibits antimycotic property through intracellular formation of 5-fluorouracil (5-FU), disrupting normal pyrimidine metabolism. It has good antifungal activity against many *Candida* species with the exception of *C. krusei*. 5-FC has been shown to have synergistic effect with azoles and amphotericin B, and are often used in tandem to treat severe infection cases. Interestingly, 5-FC excretion in urine is high. About 97% of flucytosine is excreted in the urine without structural changes. Known side effects of this antifungal drug include bone marrow suppression, GI disturbance, rash, and hepatotoxicity (Felton et al., 2014).

Treatment

Between 16.5% and 40% of candiduria diagnosed in patients being treated in ICU are caused by *Candida albicans* (>50%), followed by *C. glabrata* and *C. tropicalis* (Achkar and Fries, 2010; Alvarez-Lerma et al., 2003; Zarei-Mahmoudabadi et al., 2012). Diagnosis of candiduria due to UTI is often challenging as *Candida* spp. can also inhabit the urinary tract as a natural commensal. Consequently, this represents a therapeutic challenge confronting physicians that can be encountered ranging from asymptomatic ambulatory patients to severely ill hospitalized patients in an ICU setting. However, once candiduria is confirmed by repeat positive urine cultures and microscopy, the therapeutic options for patients vary and are dependent upon several factors such as the identity of the fungal species, the clinical status of the patient (symptomatic or asymptomatic), the severity and localization of the infection, and other intrinsic and extrinsic factors affecting the efficacy of specific antifungal drugs. New updated IDSA guidelines divide between asymptomatic and symptomatic candiduria (Pappas et al., 2016). Candiduria presented without symptoms in patients with no risk factors rarely requires therapy. A comprehensive review of patient's medical history, accompanied by additional physical examination and laboratory studies are required to obtain a full diagnostic appreciation including predisposing factors. When candiduria is linked to colonization of in-dwelling catheters, these catheters are removed to improve the condition. However, in high risk patients with symptoms, the administration of antifungal drugs is necessary to prevent the onset of invasive candidiasis, a potentially lethal complication of candiduria. If no explanation for candiduria is found, a follow-up examination of the urine is generally all that is necessary because candiduria can be expected to resolve within weeks to months without therapeutic intervention in the vast majority of individuals.

Asymptomatic candiduria

In a randomized, double-blind study (Fluconazole (200 mg) vs. placebo for 14 days) involving 316 asymptomatic candiduric hospitalized patients, candiduria recurred in 40% of the catheterized subjects and 30% of those without a bladder catheter. None of the patients in the study developed candidemia (Sobel et al., 2000). The recommendation is to eliminate predisposing factors such as discontinuation or removal of Foley catheter. Treatment with antifungal agents is not recommended unless the patient is at high risk for dissemination. Patients at risk for dissemination include neutropenic patients, very low birth weight infants (i.e., <1500 g), and patients undergoing urologic manipulation. Prophylactic use of oral Fluconazole (400 mg/day) or Amphotericin B deoxycholate (0.3–0.6 mg/kg/day) several days before and after the urologic procedure is recommended (Pappas et al., 2016). Patients with asymptomatic candiduria in ICU setting requires evaluation for the possibility of disseminated candidiasis. In this setting, 46–80% of patients with candidemia have accompanying candiduria. Removing the catheter in ICU patients resolves 20–40% and reinsertion of a new catheter can resolve in 20% of candiduria (Fisher et al., 2011b). In a large prospective study, only 7 (1.3%) of 530 patients who had candiduria and were followed for 12 weeks developed candidemia (Guler et al., 2006). In a retrospective study, 11 (10.5%) of 105 patients with candiduria developed candidemia (Lundstrom and Sobel, 2001). In a treatment trial that specifically enrolled asymptomatic or minimally symptomatic patients with candiduria, none of the 316 patients developed candidemia (Binelli et al., 2006). In the presence of an obstruction, candidemia can follow candiduria (Malani and Kauffman, 2007; Jacobs, 1996). A 1-year prospective observational study in ICUs included 262 patients with nosocomial candidemia and/or candiduria. The mean incidences of candidemia and candiduria were 6.7 and 27.4 per 1000 admissions, respectively. About 8% of candiduric patients developed candidemia with the same species (Bougnoux et al., 2008). Predisposing factors for the development of candidemia in ICU setting include neutropenia and for non-neutropenic host: prolonged broad-spectrum antibiotics, intravascular catheterization, abdominal & thoracic surgery/procedure, parenteral nutrition, and severe burn.

Discontinuing antibiotics that are no longer necessary and treating other predisposing conditions simultaneously should also be done in patients in the ICU. Antifungal treatment of candiduria in an inpatient should be reserved for those patients who have solid clinical evidence of infection of the kidney or collecting system or disseminated candidiasis. For asymptomatic candiduria, predisposed patients with strong evidence for disseminated candidiasis or unstable/neutropenic patients, the following antifungal treatments may be given: Fluconazole (400–800 mg IV/day), Caspofungin (70 mg IV loading then 50 mg/day), Anidulafungin (200 mg IV loading then 100 mg/day), Voriconazole (6 mg/kg IV q12 then 4 mg/kg q12), or Amphotericin B (0.5–0.7 mg/kg/day with or without flucytosine). For non-neutropenic patients, empiric antifungal therapy should be considered in critically ill patients with risk factors for invasive candidiasis and no other known cause of fever and should be based on clinical assessment of risk factors, surrogate markers for invasive candidiasis, and/or culture data from non-sterile sites (strong recommendation; moderate-quality evidence). Empiric antifungal therapy should be started as soon as possible in patients who have the above risk factors and who have clinical signs of septic shock (strong recommendation; moderate-quality evidence) (Pappas et al., 2016).

Symptomatic candiduria

Symptomatic candiduria may be from an ascending infection from the lower urinary tract to the upper urinary tract or via hematogenous spread to the kidneys. Patients may have cystitis and it presents as dysuria, frequency, suprapubic discomfort. They may have pyelonephritis (fever and flank pain) and rarely oliguria and stranguria due to the presence of a fungal ball. Rarely among males, they may have prostatitis, epididymitis, and orchitis. The treatment of symptomatic candiduria depends on the antifungal susceptibility of the organism and adequate antifungal concentration in the urine. About 80% of the administered dose of azole drugs remain intact in the urine. It is active against most *C. albicans* isolates.

For patients with symptomatic *Candida* cystitis, it is highly recommended (if feasible) to remove any indwelling bladder catheter, while for patients with symptomatic ascending *Candida* pyelonephritis, urinary tract obstruction (if present) must be first eliminated, or, when nephrostomy tubes or stents are in place, must be considered for removal or replacement (Pappas et al., 2016). When fluconazole-susceptible organisms are isolated from patients with symptomatic *Candida* cystitis, an oral dose of fluconazole at 200 mg (3 mg/kg) per day for 2 weeks is recommended; for patients with symptomatic ascending *Candida* pyelonephritis, an oral daily dose of 200–400 mg (3–6 mg/kg) for 2 weeks is recommended. However, when fluconazole-resistant *C. glabrata* isolates are recovered, patients with cystitis may be treated with monotherapy of either Amphotericin B deoxycholate (AmB-d) at 0.3–0.6 mg/kg per day for 1–7 days or oral flucytosine (5-FC) at 25 mg/kg 4 times per day for 7–10 days; for patients with pyelonephritis, AmB-d can be administered together with 5-FC (25 mg/kg 4 times per day) for 1–7 days. When *C. krusei* is isolated from patients with symptomatic cystitis or pyelonephritis, a daily dose of AmB-d at 0.3–0.6 mg/kg per day for 1–7 days is recommended (Pappas et al., 2016). In more severe cases where *Candida* urinary tract infection is associated with fungus balls, surgical removal is strongly recommended in adults accompanied by appropriate antifungal treatment as described for symptomatic cystitis or pyelonephritis (Pappas et al., 2016). If feasible, AmB-d can also be administered by irrigation through nephrostomy tube at 25–50 mg in 200–500 ml of sterile water (Pappas et al., 2016). The use of AmB-d bladder irrigation (50 mg/L in sterile water daily for 5 days for cases of cystitis due to fluconazole-resistant species) has not been studied in the pregnant population (Pappas et al., 2016).

Vulvovaginal candidiasis (VVC)

All common *Candida* species are capable of causing UTI and this infection and may start from an undiagnosed or untreated VVC. A gynecological assessment may be warranted to exclude the possibility of vaginal mycosis. VVC can be categorized as uncomplicated or complicated depending on clinical presentations, etiology, host response, and treatment required. Repeat urine collection for microbiological examination should be performed. A single test result with candiduria should not be a basis for therapy. If on gynecological examination, there is evidence of vaginal candidiasis, the woman should be given ideally topical, locally-acting antifungal treatment. This treatment is safe for both pregnant and non-pregnant populations (Table 1) (Tomczak et al., 2014; Malani and Kauffman, 2007). Another urine culture should be performed after treatment and if *Candida* spp. remains present, this indicates a case of urinary tract mycosis. However, a panel of microbiological tests (e.g., CRP, leukocyte count, general urine test, etc.) needs to be done and correlated with the clinical picture because the diagnosis of UTI does not rely only on the urine culture results. Due to the limited available antifungal drugs, it is always necessary to determine which part of the urinary tract is infected so that the appropriate therapy, with the appropriate drug penetration may be given (Tomczak et al., 2014).

Another problem is the non-*albicans* *Candida* UTI. These non-*albicans* fungi colonize the vulvovaginal area and are known to be resistant to fluconazole. Treatment of this complicated VVC with azoles other than fluconazole is important, in order to control the possible source of the fungi causing the UTI. Topical application of azole drugs for a limited duration of time can effectively treat uncomplicated VVC. Short-course topical formulations (i.e., single dose and regimens of 1–3 days) effectively treat uncomplicated VVC. Table 2 lists the treatment options for non-*albicans* VVC (Behzadi et al., 2010; Verma-Gaur et al., 2015; Sobel and Chaim, 1997; Sobel et al., 2003; Saxon Lead Author et al., 2020). The treatment regimen becomes more complicated when the woman is pregnant. The use of topical azoles for the treatment of superficial or intravaginal fungal infections is safe and efficacious. However, data suggest that there is a dose-dependent increased risk of teratogenicity associated with use of systemic azoles. These agents are capable of penetrating the placental barrier and entering the fetal cord blood, therefore adverse effects of these agents on the fetus are a valid concern (Moudgal and Sobel, 2003; Pilmsin et al., 2015). Systemic azoles are generally classified as pregnancy Category C or D. Voriconazole and Flucytosine are both Category D, while azoles and Echinocandins are Category C, with serious risk for fetal

Table 1 CDC recommended intravaginal regimen for uncomplicated VVC.

Drug	Prescription status	Dose per day	Duration (Days)
Clotrimazole (1% cream)	OTC	5 g	7–14
Clotrimazole (2% cream)	OTC	5 g	3
Miconazole (2% cream)	OTC	5 g	7
Miconazole (4% cream)	OTC	5 g	3
Miconazole (200 mg, suppository)	OTC	1 suppository	3
Miconazole (1200 mg, suppository)	OTC	1 suppository	1
Tioconazole (6.5% ointment)	OTC	5 g	1
Butoconazole (2% cream)	Prescription	5 g	1
Terconazole (0.4% cream)	Prescription	5 g	7
Terconazole (0.8% cream)	Prescription	5 g	3
Terconazole (80 mg, suppository)	Prescription	1 suppository	1

Table 2 Treatment options for complicated Non-*albicans* VVC.

Drug	Prescription status	Dose per day	Duration (Days)
<i>C. glabrata</i>			
Boric acid (600 mg, suppository)	Prescription	5 g	7–14
Nystatin (100,000 units tablet)	Prescription	5 g	14
Flucytosine cream (17% cream) or Amphotericin B cream (3%)	Prescription	5 g	14
<i>C. krusei</i>			
Clotrimazole (1% cream)	OTC	5 g	7–14
Clotrimazole (2% cream)	OTC	5 g	3
Miconazole (2% cream)	OTC	5 g	7
Miconazole (4% cream)	OTC	5 g	3
Miconazole (200 mg, suppository)	OTC	1 suppository	3
Miconazole (1200 mg, suppository)	OTC	1 suppository	1
Boric acid (600 mg, suppository)	OTC	1 suppository	14
Itraconazole (100 mg, capsule)	Prescription	200 mg (2 ×)	7–14
Ketoconazole (200 mg, tablet)	Prescription	200 mg (2 ×)	7–14

malformations. There is insufficient data regarding the use of caspofungin in pregnancy (Moudgal and Sobel, 2003; Pilimis et al., 2015). Fluconazole has been found to be embryo-toxic and teratogenic in rodents and rabbits. Fluconazole dose of >300 mg is considered teratogenic and remains contraindicated during pregnancy. However, a single low dose (total dose of <300 mg) does not increase the risk of congenital disorders. This low dose fluconazole may be considered as systemic antifungal treatment in the absence of topical alternative, beyond first trimester, especially in cases of VVC (Moudgal and Sobel, 2003; Pilimis et al., 2015).

Concluding remarks

As discussed in this review, fungal-related urinary tract infections that predominantly are due to *Candida* spp. are common although their medical and socioeconomic impact is likely underestimated. The development of UTI as a result of *Candida* spp. switching from a benign commensal to a pathogenic agent is a complex process and is influenced by different factors such as the health and immune status of the host, expression of virulence factors, interaction with competing microbiota, and the presence of robust nutrient acquisition and metabolic machinery. The treatment of fungal UTI is challenging and highly variable depending upon several factors such as variation in clinical manifestations of the disease among different risk groups, limited antifungal drugs, emergence of fluconazole-resistant non-*albicans* *Candida* species (NACS), and thus must be used with utmost consideration. Although *C. albicans* constitutes most of the reported cases of fungal UTI, it is likely that UTI cases due to NACS or even other fungal species is under-reported highlighting the need to develop more reliable diagnostic procedures. Clearly, there are several important aspects of fungal-related UTI that need to be resolved in order to get a clearer overall picture of its impact in the society.

Urinary tract infections

Urinary tract infections (UTIs) are the inflammatory disorders of the urinary tract caused by the abnormal growth of pathogens causing short-term morbidity in terms of fever, dysuria, and lower abdominal pain (LAP) and may result in permanent scarring of the kidney (Odoki et al., 2019). These symptoms may occur as a result of delayed and inadequate treatment (Gökçe et al., 2017). UTIs are commonly classified by the site of infection (the bladder [cystitis], kidney [pyelonephritis], or urine [bacteriuria]) and can be asymptomatic or symptomatic, characterized by a wide spectrum of symptoms ranging from mild irritative, bacteremia, sepsis, or even death (Nicolle, 2002).

UTIs are caused by a range of pathogens the most common ones include *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Enterococcus faecalis* and *Staphylococcus saprophyticus*. UTIs are one of the most common infections in childhood (Leung et al., 2019). Antibiotic treatment is the mainstay treatment of UTI and is effective in reducing the morbidity caused by UTI (Yüksel et al., 2006). However, there is a growing concern over antibiotic resistance in many parts of the world (Gökçe et al., 2017; Yüksel et al., 2006).

In this chapter we will be focusing on urinary schistosomiasis which affects mostly the urinary bladder, the lower ends of the ureters, and the seminal vesicles. Urinary schistosomiasis is one of the neglected tropical diseases and therefore the need to look at it apart from the common UTIs.

Schistosomiasis

Human schistosomiasis or bilharzia is a parasitic infection that is caused by trematode flukes of the genus *Schistosoma*. Approximately 250 million people are infected with *Schistosoma* species worldwide (Colley et al., 2015). Urogenital schistosomiasis caused by *Schistosoma haematobium* is endemic in 53 countries in the Middle East and most of the African continent and results in 150,000 deaths annually in sub-Saharan Africa (Hammad et al., 2018). Schistosomiasis is a neglected tropical disease (NTD) which represents a group of 17 major debilitating diseases. These diseases thrive among the poor, increase poverty by reducing, marring, stigmatizing, isolating victims and destroying their ability to learn, work, and contribute to their families and the nation at large (Karunamoorthi et al., 2017).

Schistosomiasis is particularly common in poor communities without access to safe drinking water and adequate sanitation (Weerakoon et al., 2015); as a result people at the highest risk of infection are persons involved with agricultural, domestic and recreational activities, which expose them to contaminated water. Schistosomiasis infection prevalence and intensity curves show peaks in children aged 6–15 years and decline gradually with age, hence, the current global strategy emphasizes preventive chemotherapy to reduce morbidity, which primarily targets school-age children (Coulibaly et al., 2013). Children are mainly at risk of *Schistosoma* infection (Fig. 1) as they engage in multiple high-risk behaviors for acquiring schistosomiasis because of poor knowledge on disease transmission, lack of understanding on the severity of disease-associated consequences, and lack of alternatives for water-related activities of daily living and recreational play (Person et al., 2016). There are 2 types of schistosomiasis affecting humans, intestinal and urogenital schistosomiasis caused by five main species of blood fluke which are *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma mekongi*, *Schistosoma intercalatum* and *Schistosoma haematobium*. The most common forms are *Schistosoma haematobium*, *Schistosoma mansoni*, and *Schistosoma japonicum*.

Urogenital schistosomiasis

S. haematobium which is most prevalent in Africa and the Middle East causes urogenital schistosomiasis (Darren and Weerakoon, 2013). Deposit of human waste in water containing intermediate hosts is the single most important epidemiological factor in transmission of schistosomiasis and the availability of a suitable snail host. The transmission of schistosomiasis is associated with water development projects including dams for irrigation and fish-farming, as snails infected with *Schistosoma* breed in them and human water contact also takes place in such water bodies. Urogenital schistosomiasis being a water-based disease is spread through contact with contaminated water in which snails harbor and shed the infective cercariae are present (Nwele et al., 2017).

Typical symptoms are blood, protein and leukocytes in urine, nutritional deficiencies, lesion of the bladder, kidney failure, and child growth retardation (Afiukwa et al., 2019). In areas of overall high levels of infection, urogenital schistosomiasis is known to peak in the 6–20 age groups with areas of lower levels of infection more prevalent in older age groups which is attributed to the development of acquired immunity (Mitchell et al., 2011).

Transmission of *Schistosoma* spp.

Transmission of the *S. haematobium* or *S. mansoni* parasite starts when infected people with urinary schistosomiasis contaminate freshwater sources with urine that contains the eggs of *S. haematobium* which hatch in the water to form miracidia. Miracidia infect the species-specific intermediate hosts, freshwater snails of the genus *Bulinus* (*S. haematobium*, *S. intercalatum* and *S. guineensis*), *Biomphalaria* (*S. mansoni*), *Oncomelania* (*S. japonicum*) and *Neotricula* (*S. mekongi*). The miracidia multiply asexually in the intermediate hosts. Although most *Schistosoma* species have humans as the only definitive host, *S. japonicum* may infect a wide range of domestic and wild animals, including cattle, dogs, pigs, water buffaloes and rodents. The cercariae are produced in the snail and invade the human via percutaneous penetration (Bourke et al., 2013). After penetration, cercariae migrate from the skin into the portal vein, where they reach adult stage, mate and migrate to the venous plexus of the bladder and genitals and start producing eggs (European Centre for Disease Prevention and Control, 2015).

Fig. 1 School going children at risk of Schistosomiasis. Many communities rely on nearby rivers or dams for water for carrying out household chores such as laundry in (A). These water sources are likely to be contaminated by the *Schistosoma* parasites. The water bodies also provide recreational activities like swimming in (B).

The adult female and male worms reside in permanent pairs in the perivesical for *S. haematobium* or portal veins and mesenteric blood vessels for other *Schistosoma* species (Knopp et al., 2013). Eggs produced by the female *S. haematobium* or *S. mansoni* worms reach the bladder or intestine respectively, from where they can be excreted with urine or feces. The laying of eggs causes damage to the walls of the bladder and genital tissues in the form of lesions in blood vessels and tissues leading to the common symptom of blood in urine known as hematuria (Appleby et al., 2012; Ekpo et al., 2010). A later stage of clinical pathology called hepatosplenic schistosomiasis (HSS), is frequently seen in endemic areas (Gasim et al., 2015). Most clinical patterns of the infection depend on the interaction of various factors including strain of parasite, host genetic background, host immunity and nutritional status, and co-infections.

Prevention and control of schistosomiasis

The main method of preventing *Schistosoma* infection is avoiding contact with fresh water infested with *Schistosome* parasites including avoiding swimming, wading, or any other aquatic activities in *Schistosoma*-contaminated sources, which exposes the skin to possible penetration by the cercariae (Inobaya et al., 2014). Topical lipid formulations of N, N-diethyl-m-toluamide (commonly known as DEET) are highly effective in killing schistosome cercariae on the skin (Ramaswamy et al., 2003).

The lifecycle of schistosome can be interrupted by chemotherapy, intermediate host control, and the complementary roles of water sanitation and hygiene (WASH) (Braun et al., 2018). Zimbabwe launched a mass drug administration (MDA) program against schistosomiasis and soil-transmitted helminths in WHO | Zimbabwe (2012). The MDA program is very effective and is the main method used for killing the adult worm using PZQ, however PZQ does not prevent reinfection (Braun et al., 2018). Control of the intermediate host in Zimbabwe was done using methods including mollusciciding with niclosamide which was implemented in the Kariba dam and Hippo Valley estate. Other methods of controlling the intermediate host include plant-based molluscicides, also controlling snails using biological agents such as ducks, fish or competitive snails (Chimbari, 2012).

Data from the 2012 National Population Census in Zimbabwe show that more than 40% of the family households do not have any type of toilet facility with the majority of the population being the rural population which practices open defecation (UNICEF Zimbabwe, 2019). The WASH programs that are being implemented in Zimbabwe may reduce the prevalence of schistosomiasis if programs are integrated. WASH reduces transmission by containing schistosome eggs and reducing human water contact. People with safe water and adequate sanitation have been shown to be less likely to have *Schistosoma* infection (Grimes et al., 2015).

Diagnosis of schistosomiasis

Schistosomiasis can be diagnosed by direct or indirect methods. All of which have limitations. Direct parasitological methods of schistosomiasis involve the detection of parasite eggs in fecal or urine samples or in the tissues or detection of schistosome-derived antigens in the circulation and excreta. Indirect immunological tests are used to detect the specific antibodies induced against the different stages of the parasite in blood (Lu et al., 2012). Microscopic examination of eggs in urine is currently considered gold standard of detecting *Schistosoma*. *S. haematobium* eggs are released in urine and are detected by microscopy in a sample of urine concentrated by sedimentation, centrifugation, or by filtration forced through a nitrocellulose filter. A urine sample is preferably collected between 10 am and 2 pm to coincide with the maximum excretion of eggs. Reported blood in the urine and micro-hematuria on reagent strips indicates potential infection in those living in endemic areas (Gray et al., 2011). Other methods include microscopic examination of tissue biopsies, serological and reagent strip diagnosis of circulating parasite proteins detectable in blood and urine and, more recently, detection of parasite DNA in urine or vaginal lavage samples (Mutapi, 2011). Methods such as detection of hematuria (blood in the urine) and proteinuria (protein in the urine) which results from the passage of parasite eggs through the bladder wall. Ultrasound scans of the urinary tract are also used to detect morbidity but are less practical in the majority of field settings owing to the requirement of specialized equipment and trained personnel. Microscopic methods of diagnosing schistosomiasis are cheap, time-consuming and have poor sensitivity, hence, sensitive serological tests have the potential to increase diagnostic yield, especially in those with light infection who excrete few eggs (Turner et al., 2004). The specificity of currently available serological tests for the diagnosis of schistosomiasis is generally reduced due to cross-reactivity, making it impossible to differentiate between schistosomiasis and infections with some other helminths (Hinz et al., 2017). The sensitivity of antibody-detection methods was previously shown to decline in areas of low infection. Despite the decline in sensitivity, antibody detection methods remain one of the best available tools for diagnosis in areas of low infection (Nausch et al., 2014).

Praziquantel (PZQ)

Urinary schistosomiasis, as for other types of schistosomiasis, can be treated with praziquantel (Kay et al., 2015). Praziquantel (PZQ) is a pyrazinoisoquinoline derivative (Vale, 2017). PZQ was first used in the 1970's to treat veterinary cestode and trematode infections (Andrews et al., 1983). PZQ has been utilized to treat an assortment of human trematode diseases and is presently the medication of choice for all types of schistosomiasis. PZQ cannot be used for chemoprophylaxis because of its short half-life (1–1.5 h) and cannot kill migrating larvae that are three to 21 days old (McManus et al., 2009). With over 30 years in use the precise mechanism of action of PZQ is not known (Aragon et al., 2009). However, the effects of the drug on schistosomes have been reported where it has been shown that PZQ may interrupt inorganic ion transport. When male *S. mansoni* interacted with PZQ in vitro, the parasite instantly experienced an intense muscular paralysis that was accompanied by a rapid influx of calcium ions, a slower influx of sodium ions and potassium ions (Pax et al., 1978). PZQ disrupts the worm tegument which leads to the exposure of antigens on the parasite surface this has been linked to the disruption of calcium ion homeostasis. It has been proposed that the mechanism of action of PZQ involves alteration of the schistosome membrane fluidity, reduction of schistosome glutathione concentration enabling the host immune system to be more effective, binding to schistosomal actin leading to tegument disruption as well as inhibition of nucleoside uptake.

PZQ is widely metabolized by cytochrome P450 (CYP) enzymes where the CYP3A are most likely to be the major enzymes responsible for PZQ metabolism. Rifampicin was shown to significantly decrease plasma concentrations of single and multiple oral doses of PZQ to levels lower than that of the minimum therapeutic concentration. An example is in Thailand where rifampicin is used for the treatment of tuberculosis and PZQ for the treatment of liver flukes (Ridititid et al., 2002). In this way, the use of both rifampicin and PZQ must be avoided in medical practice to maximize the therapeutic efficacy of PZQ. Joint administration of PZQ and grapefruit juice could lead to a further improvement in the effectiveness of PZQ therapy by enhancing the bioavailability of PZQ (Castro et al., 2002).

Resistance to praziquantel

PZQ replaced all other anti-schistosomal drugs and is the only drug that is currently used for the treatment of schistosomiasis for the past 30 years and the emergence of drug resistance could be a major concern (Wang et al., 2012). The repeated use of PZQ to reduce worm burden makes the evolution of resistant worms a possibility (Melman et al., 2009). Worm reproduction in the mammalian host is sexual and the generation time is relatively long, resistance is likely to take many years to become an important clinical and public health issue (Gray et al., 2011).

Surveys conducted on Egyptian villagers where PZQ has been heavily used show that *S. mansoni* has gained resistance to PZQ. *S. mansoni* has been shown to have gained resistance to PZQ among the Kenyan and Senegalese (Melman et al., 2009; Southgate, 1997). The global burden of schistosomiasis may have increased over the last three decades despite of the regular MDA with PZQ suggesting that MDA with PZQ alone will not be adequate for the global elimination of schistosomiasis (Merrifield et al., 2016). Research should continue on developing alternative drugs (Gray et al., 2011). Currently there is no vaccine for schistosomiasis hence, a need to increase efforts in understanding the immunological responses when one is infected and treated with PZQ.

In the preschool age children (PSAC) there is lack of information as to prescribing PZQ by pharmaceutical companies on toxicity, method of administration, adverse effects and pharmacokinetics which may result in clinical disease that is not managed (Kimani et al., 2018). The oral bioavailability of drugs might vary in PSAC and adult populations due to differences in gastric pH and emptying time, intestinal transit time, immaturity of secretion, and the activity of bile and pancreatic fluid. Further, the drug distribution in children and adults differs as well as the immaturity of enzyme systems (cytochrome P450), glomerular filtration, renal tubular secretion, and tubular reabsorption in children account for a different excretion of drugs in the pediatric population compared with adults (Coulibaly et al., 2017). Praziquantel in adults is mainly used at 40 mg/kg body weight it may be beneficial to carry out a survey using a 20 mg/kg, 40 mg/kg and 60 mg/kg concentration of PZQ to obtain the most effective dosage to be used for the preschool-age children.

Immune response to schistosomiasis

During acute schistosomiasis, before the appearance of eggs in the urine or stool, there is a dominant T-helper 1 (Th1) response characterized by the production of large quantities of Tumor necrosis factor alpha (TNF- α), interleukin 1 and 6 (IL-1 and IL-6) by peripheral-blood mononuclear cells (PBMCs). As the disease progresses the developing egg-antigen induces a T-helper 2 (Th2) response which downregulates the production and effector functions of pro-inflammatory mediators (Pearce and MacDonald, 2002). Raising an immune response has harmful effects that include damage to host's immune system. The evolution of a beneficial immune protection has had to develop alongside potentially lethal damage that immune responses can cause, namely immunopathology (Zinkernagel and Hengartner, 2001).

T helper 1 response

T helper type 1 (Th1) responses have been shown to provide protective immunity against schistosome infection (Butterworth, 1968). Although Th1 immune responses are important in providing protective immunity against schistosome infection, a rapidly induced and excessive Th1 response may also cause damage to tissues of the infected host during parasite killing (Pearce and MacDonald, 2002; Xu et al., 2010).

Interferon gamma (IFN γ) and TNF- α are regarded as markers of the Th1 and pro-inflammatory response. Other cytokines involved are IL-1 and IL-6 which are part of the acute phase of infection (Badr et al., 2015). The pro-inflammatory response is needed to hinder the multiplication of the parasite and favor its clearance in human and animal models. While important for parasite clearance a powerful Th1 and pro-inflammatory response could also be detrimental for the host if uncontrolled, leading to tissue damage and severe disease (Ateba-Ngoa et al., 2015).

T helper 2 response

T helper type 2 (Th2) responses provide a double role in schistosomiasis, to mediate granuloma formation and to regulate inflammation (Riner et al., 2013). Chronic helminthiasis is usually characterized by a marked Th2 response as well as by the induction of a regulatory network that could consequently impair the host immune response to other antigens (Ateba-Ngoa et al., 2015). The Th2 response is characterized by low levels of IFN- γ , and high production of IL-4, IL-5, IL-13, and IL-10 (Badr et al., 2015). IL-10 is a key anti-inflammatory, anti-immune, and anti-fibrotic cytokine secreted by Th2 cells, and it is responsible for the regulation of the inflammatory response and modulation of hepatic fibrogenesis (Silva et al., 2014).

Hygiene hypothesis

The hygiene hypothesis states that increased exposure to microbes early in life may prevent allergic diseases and the theory was first proposed by Strachan, who observed an inverse relationship between hay fever and the number of older siblings when following more than 17,000 British children born in 1958 (Okada et al., 2010). The hygiene hypothesis proposes that the stimulation of the immune system by microbes protects from the development of inflammatory diseases; therefore a reduced exposure to infectious agents may explain the rise in allergic and autoimmune diseases in industrialized countries (Yazdanbakhsh and Matricardi, 2004).

Parasitic infections are a major aspect of the hygiene hypothesis, as allergies and autoimmune diseases are less prevalent in countries with higher burdens of helminths and other parasitic organisms. Helminths establish chronic infections indicating successful down modulation of the host immune system resulting in lower immunopathology, reduce host susceptibility to, and severity of allergic and autoimmune diseases (Wilson and Maizels, 2004). Studies in mice have established that regulatory immune responses induced by helminth can suppress Th2 and Th1 or Th17 responses that mediate allergy and autoimmunity, respectively. The studies in mice have provided an explanation for the hygiene hypothesis' and have led to the exploitation of helminths or their immunomodulatory products in the development of new immunosuppressive therapies for inflammatory diseases in humans (Finlay et al., 2014). Helminth products generate regulatory responses capable of inhibiting not only anti-parasite immune responses but also allergic sensitization (Rujeni et al., 2012). Helminth infections and allergic diseases are both associated with Th2 cytokines and high levels of immunoglobulin E (IgE) and eosinophilia (De Oliveira et al., 2014).

Antinuclear antibodies (ANA) are a spectrum of auto antibodies targeted to various nuclear and cytoplasmic components of the cells and are useful serological markers for different autoimmune disease, like Systemic lupus erythematosus (SLE), Sjögren's syndrome (SS), scleroderma, polymyositis, or mixed connective tissue disease (Vlagea et al., 2018). We measured ANA and their relation to schistosomiasis (Chimponda et al., 2019). We found levels of the antinuclear antibodies to be significantly higher in schistosome-uninfected children than infected children. Furthermore, *S. haematobium* infection intensity inversely associated with antinuclear antibody levels supporting the hygiene hypothesis.

Pediatric schistosomiasis

Probably from as early as 1898 it has been reported that children 5 years and below were infected with schistosomiasis (Bustinduy et al., 2017). Investigators have reported prevalence rates of pediatric schistosomiasis infection ranging from 18% to 63% in Mali, Niger, Sudan, Uganda and Zimbabwe (WHO, 2010). Children under 5 years of age are often exposed daily to infected water very early in life, although infection is not apparent, infection generates inflammation that predisposes to organ fibrosis, which can endure for many years (Colley et al., 2015).

Water infested with the cercariae may be used in bathing the children, putting the children at risk of infection to *S. haematobium* despite not having been in contact with the river. The justification for the neglect in treatment of young children is that, the group was considered a non-infected to lightly infected population and therefore thought to be at low risk for schistosomiasis-associated morbidity; as well as lack of a child-friendly formulation for oral treatment that would decrease the risk of choking (Bustinduy et al., 2017). Other problems which resulted in the exclusion of this group include operational problems associated with accessing preschool children and lack of information on the safety of the drug of selection for schistosome management, PZQ, in children aged 5 years and below (Mutapi et al., 2011). The first expert meeting on the inclusion of preschool-age children in schistosomiasis control efforts was convened at the WHO in 2010. Strong evidence emerged that very young preschool-age children do indeed harbor egg-patent infection (Bustinduy et al., 2017). These children are both at risk of infection and a potential reservoir for the parasite in communities successfully targeted by mass anti-helminthic drug treatment (Mutapi et al., 2011). Early care for and attention to children 5 years old and below may provide an opportunity to treat schistosomiasis-associated anemia, reduce occult blood loss and reduce inflammatory responses (Mduluzza et al., 2017). Fig. 2 is a picture showing PSAC at risk of *S. haematobium* infection.

When dealing with schistosomiasis in pediatrics we have to look at the wholistic picture. Fig. 3 shows some issues that come with pediatric schistosomiasis.

Co-infections with schistosomiasis

Schistosomiasis exists in communities that are infected with other pathogens. Schistosomiasis and malaria exhibit almost similar distribution patterns, making coinfection a predominant occurrence in malaria endemic countries where there is very high poverty (Ojo et al., 2019). Many studies have been carried out revealing the co-infection of schistosomiasis with other diseases on adults but there is still a gap on the effects of co-infections of *S. haematobium* with other pathogens in PSAC (Mduluzza-Jokonya et al., 2020). In a study multiple parasite infections were prevalent in school and PSAC of Magu district in Tanzania and these coinfections result in poor growth development, reduced learning and school achievements as well as increased susceptibility to other infections (Kinung'hi et al., 2014).

Children in Senegal with a light *S. haematobium* infection (1–9 eggs/mL of urine) presented significantly lower *P. falciparum* parasite densities than children not infected by *S. haematobium* showing that schistosomiasis is protective to malaria (Lemaitre et al., 2014). Schistosomiasis induces a polarized Th2-enriched environment which modulates the human immune response, possibly affecting the incidence and severity of concomitant falciparum malaria (Lyke et al., 2006). Anemia has been proposed as a marker for morbidity reduction in schistosomiasis control programs because it is easy to quantify and is affected by presence and intensity of schistosome infection, however, the contribution of schistosomiasis to anemia is concealed by anemia due to malaria therefore should not be used to determine the impact of a *Schistosome* program in populations of malaria and schistosomiasis coinfections (Valice et al., 2018).

Schistosomiasis appears to promote an increased susceptibility to HIV, a more rapid disease progression, and transmission of HIV to others by stimulating the Th2-type cytokine production that leads to eosinophilia in contrast with the Th1-type response in

(A)

(B)

Fig. 2 PSAC are at risk of schistosomiasis. Pediatrics at a water source suspected to be contaminated with snails infested with *S. haematobium* parasites in (A). Mothers or care givers often bathe their young children in the dams or rivers as shown in (B).

Fig. 3 Paediatric schistosomiasis and its complications. PSAC living in areas where schistosomiasis is endemic also suffer from malnutrition and are subject to other infections such as malaria and HIV. This age group has underlying inflammatory conditions and also receive vaccinations, whose efficacy may be affected by the infection.

lymphocytes, which is reduced leading to a less efficient control of HIV replication in the host (Knopp et al., 2013). HIV infection comes before schistosomiasis in infants and young children, whereas in adults schistosomiasis precedes HIV (Bustinduy et al., 2014). Children with light intensity of *Schistosoma* infection may have compromised immune systems from HIV infection (or other immune deficiencies), which impairs efficient egg excretion and, for this reason alone, HIV infection should be considered as a possible contributing factor on the rate of egg excretion (Bustinduy et al., 2014). This has a direct bearing on diagnosing schistosomiasis. In that case the urine filtration method which is used mostly to diagnose *S. haematobium* infection in these low resource areas because it is cheap may have to be combined with other techniques such as serology in order to identify these children with light infections.

Schistosomiasis and malnutrition

Malnutrition refers to deficiencies, excesses, or imbalances in a person's intake of energy and/or nutrients and applies to three groups of conditions such as undernutrition, micronutrient and overweight (WHO, 2020a,b). It was estimated worldwide that one in every three preschool children is malnourished (Wong and Nair, 2014). According to WHO 47 million children under 5 years of age are wasted, 14.3 million are severely wasted and 144 million are stunted, while 38.3 million are overweight or obese (WHO, 2020a,b). Malnutrition among children is a marker of development and represents the socio- economic status of populations (Payandeh et al., 2013).

Parasitic infections cause anorexia and poor absorption of nutrients and promote the deviation of nutrients to the organism's defense mechanisms and contribute to the onset or exacerbation of weight and height deficits (Mekonnen et al., 2014). Blood losses from hematuria and fecal occult blood from schistosomiasis affects iron balance and subsequently nutrition (Adeniran et al., 2017). *S. haematobium* causes losses of a milligram or more of iron a day and the amount of iron lost by children infected with *S. haematobium* can be similar to daily menstrual losses of iron averaged out over a month (Hall, 2007).

Iron deficiency impairs the immunity, increases the susceptibility of infected individuals to reinfection with schistosomiasis and other tropical diseases (Mwanakasale et al., 2009).

Factors affecting growth and development of preschool children are well-documented (Mekonnen et al., 2014). However, since the PSAC are now being considered for treatment for schistosomiasis we need to revisit the issue of malnutrition. In a population receiving multi-micronutrient supplementation along with broad spectrum anti-parasitic anthelmintic treatment saw reduced infestation with *Schistosoma* spp. (Morales-Suarez-Varela et al., 2019). The gap that may need to be filled is that instead of treating the PSAC with PZQ only it may be necessary to supplement the treatment with micronutrients. The benefits of micronutrient supplementation with PZQ treatment have been shown in other studies. Mwanakasale et al. (2009) showed that providing iron supplements once a week decreased reinfection of *S. haematobium* after 6 months in school age children. Supplementing with micronutrients was shown to reduce the side effects of PZQ treatment in swiss female albino mice.

Childhood vaccinations and schistosomiasis

PSAC receive vaccinations from diseases such as tuberculosis, measles, rubella, diphtheria, tetanus and whooping cough. There is clinical evidence to suggest that chronic prenatal parasitic infection as well as parasitic infections in the first few years of life can highly alter infant immune responses to standard childhood vaccinations (Labeaud et al., 2009). Helminth-induced immunomodulation reduces host responses, allowing parasite survival and minimizing tissue damage and this immunomodulation may also alter responses to unrelated organisms and vaccines (Elliott et al., 2007).

Studies on the effect of schistosomiasis on response to vaccines need to be undertaken for the PSAC. Twayongyere et al. (2019) found that *S. mansoni* infection among pre-school children is associated with a reduced antibody response to catch-up measles immunization, and that PZQ treatment improves the response. *S. mansoni* infection was shown to reduce the protective efficacy of BCG vaccination against *M. tuberculosis* (Elias et al., 2005). Nono et al. (2018) found lower immune responses to measles vaccine in *S. mansoni* infected participants than uninfected participants which was not observed in *S. haematobium* infected participants. According to (Hartmann et al., 2019) helminth infection reduces the quantity and quality of antibody responses to vaccination against seasonal influenza. This implies that considerations have to be made when designing vaccines to be utilized by individuals living in areas where helminths are endemic.

Inflammation in schistosomiasis

Inflammation is the body's way of signaling the immune system to heal and repair damaged tissue and defend itself against foreign invaders, such as viruses and bacteria. Inflammation can be a fundamental factor in the development of a disease (Malenica et al., 2017). In chronic *S. haematobium* infections, eggs lodged in the urinary tract elicit immune responses that result in inflammatory cell infiltration, granuloma formation, urinary tract fibrosis and renal dysfunction (Njaanake et al., 2014). Antigens produced by viable ova in tissues stimulate a host driven granulomatous inflammation that disrupts the epithelial barrier of the bladder, which permits ova to move from the venule into the lumen of the bladder. The inflammatory process results in varying degrees or collateral damage to tissues, and the extent of this damage is accompanied by the intensity of the granulomatous response and its anatomic location. Inflammation at the site where the ureter enters the bladder may obstruct the ureter, leading to a dilation of the ureter, calyces of the kidney, and eventual kidney failure (Wamachi et al., 2004). In schistosomiasis, excessive inflammation and cytokine production are associated with severe immunopathology and mortality.

Inflammatory markers

Measurement of inflammatory markers is used to detect acute inflammation that might indicate specific diseases or to give a marker of treatment response (Watson et al., 2012). Biomarkers of inflammation if identified early may allow for better prognosis (Chisango et al., 2018). Inflammatory markers are good diagnostic markers especially for diseases which do not show any clinical symptoms and help to diagnose and possibly predict disease outcome (Kiszevska et al., 2015). Identification of additional biomarkers for detection of schistosomiasis related morbidity would be an invaluable tool for schistosome control programs, especially in schistosome infections where such markers may facilitate timely treatment to prevent severe morbidity (Vennervald et al., 2000). *Schistosoma* infection is known to induce inflammatory reactions in the host leading to changes in serum concentrations of immunoglobulins as well as acute phase proteins (Salawu and Arinola, 2010). IL-6 is the major regulator of the acute phase response in hepatocytes and promotes the systemic effects of the acute phase response by stimulating the growth and differentiation of many cell types (Bresnahan and Tanumihardjo, 2014).

There are different types of inflammatory markers such as cytokines, reactive oxygen species and acute phase proteins such as serum amyloid A (SAA) and C-Reactive Protein (CRP) (Brenner et al., 2015). Acute phase proteins are plasma proteins whose concentrations increase by at least 25% during inflammation states (Gabay and Kushner, 1999). The acute phase response accompanies both acute and chronic inflammatory states. Conditions that normally lead to substantial changes in the plasma concentrations of acute-phase proteins include infection, trauma, surgery, burns, tissue infarction, various immunologically mediated and crystal-induced inflammatory conditions, and advanced cancer (Gabay and Kushner, 1999). Identification of additional biomarkers for detection of schistosomiasis related morbidity would be an invaluable tool for schistosome control programs, especially in schistosome infections where such markers may facilitate timely treatment to prevent severe morbidity (Vennervald et al., 2000). In a study on inflammatory markers in *S. haematobium* infection, we measured levels of Resistin, P-selectin and CRP in PSAC living in a *Schistosoma* endemic area. We found P-selectin to be significantly associated with *S. haematobium* infection and that infected participants had significantly higher levels of this marker than uninfected children and hence a potential biomarker of *S. haematobium* infection. Participants exposed to cercarial antigens also had higher levels of P-selectin, Resistin and C-reactive protein showing an underlying inflammatory condition (Chimponda et al., 2019).

NTDs including urogenital schistosomiasis in the era of COVID-19

The world's attention and focus is on COVID-19 and many diseases have been left out including the already neglected tropical diseases (Molyneux et al., 2020). COVID-19 has brought with it many problems including access to chemotherapy for urinary schistosomiasis as many countries were on strict lock downs. The WHO has designed a frame work for implementing MDA programs for NTDs. The proposed process relies on two steps: a risk-benefit assessment, to decide if the planned NTD activity should proceed, and an examination of a list of precautionary measures, to decide how the planned activity should be implemented (WHO, 2020a,b). MDA programs have thus been put on hold as deliberations on how to best carry out these programs are being discussed. The milestones that have been reached especially in the context of pediatric schistosomiasis have been derailed. According to (Toor et al., 2020), schistosomiasis, STH and trachoma found in high transmission areas are bound to have a fast resurgence impacting the gains made of the MDA programs up to 2020 and are bound to affect the 2030 goals. COVID-19 has also impacted on the manufacturing of rapid diagnostic tools (RDT) for many neglected tropical diseases with many RDTs being made for COVID-19 diagnosis (de Souza et al., 2020). The lessons learnt from the manufacturing of RDTs for COVID-19 must now be implemented for schistosomiasis.

Other concerns are that co-infection of pre-existing infection with any parasitic infection with SARS-CoV-2 may lead to changes in susceptibility and/or severity of COVID-19 (Gutman et al., 2020). (Ssebambulidde et al., 2020) have given a possible hypothesis for the comparatively low COVID-19 cases/deaths in parasite-endemic areas such as Africa is the immunomodulation induced by parasites.

Concluding remarks

Schistosomiasis will continue to be with the poor and causing devastating effects especially to the young still growing up. Mass treatment may be the only interim control measure, to reduce development of severe morbidity and pathology. Mass treatment through MDAs is not sustainable especially in communities where the governments are already riling under poverty and failing to provide basic health services to its populations. Integrated control strategies need to be devised that target several of the prevalent neglected tropical diseases in the tropical regions. With the spread of SARS-Cov2, the poor communities may have exacerbating conditions due to an already inflammatory status. However, more work is required to understand the contribution of the NTD prevalences and incoming of SARS-Cov2. The most urgent requirement is to integrate NTDs control with WASH program as most of the NTDs are related to poor wash conditions. However, health education need to be intensified and prevent the continued deposition of waste and unhygienic conditions in the communities, and intensify the supply of medicines to cut the *Schistosoma* life cycle.

Gastrointestinal bacterial infections

Gastrointestinal (GI) infections, including diarrheal diseases and infections of the gastric pathogen *Helicobacter pylori*, are very common in regions of the world with poor water sanitation and cramped living conditions. Outbreaks of, e.g., cholera or bacterial dysentery, might occur in refugee camps and after flooding or earthquakes when access to clean potable water and sanitation is scarce; however, these diseases are also endemic in several regions and are able to cause pandemics. Food poisoning and gastroenteric problems such as inflammatory bowel disease (IBD), inflammatory bowel syndrome (IBS), and nosocomial antibiotics-induced *Clostridioides difficile* infections (CDI) are common globally and are associated with bacterial dysbiosis in the GI tract and severe health problems. Hence, gastrointestinal infections include a large number of bacterial species that cause a variety of symptoms. In addition, although not addressed in this article, it is important to remember that viruses and parasites are also major causative agents of gastroenteric infections worldwide.

*The authors contributed equally.

Food poisoning and foodborne gastroenteritis

Foodborne bacterial infections are common globally and can cause a range of diseases, from diarrhea to cancer. Foodborne infections are often spread by contaminated food or drink and can cause regional outbreaks or epidemics, affecting larger areas and populations. Several of the most common foodborne bacterial pathogens can cause both epidemics and pandemics. Diarrheal diseases, particularly affecting people living in low-income regions, are often endemic but may cause seasonal epidemic peaks; this will be described separately below.

According to World Health Organization (WHO), enterohemorrhagic *E. coli* (EHEC), *Salmonella enterica* serovar Typhimurium, and *Campylobacter* spp., are the most common causes of bacterial foodborne gastroenteritis globally and cause similar symptoms including bloody dysenteric stools and inflamed epithelium, abdominal pain, and fever. Other foodborne diseases are common also in high-income regions and include acute food poisoning or intoxication caused by bacterial toxins that remain in food after preparation. Such enterotoxins are produced by species such as *Staphylococcus aureus*, *Clostridium perfringens*, and *Bacillus cereus*. They may cause acute nausea and vomiting as well as diarrhea within less than an hour after ingestion. Symptoms of foodborne infections range from mild problems to potentially life-threatening conditions caused by cholera, listeriosis, or botulism.

Campylobacter

Campylobacteriosis is the most common gastroenteritis globally, and it is caused by *Campylobacter*. The genus *Campylobacter* encloses Gram-negative and microaerophilic bacterial species, including *Campylobacter jejuni* and *Campylobacter coli*. They may be present in raw milk, water, and raw poultry and are considered as zoonotic bacteria that can spread by improper handling of meat after slaughter. The onset of bloody diarrhea, abdominal pain, and fever typically occur after 2–5 days. Most infections are mild and not life-threatening, but young children and immunocompromised persons may get severe symptoms. *Campylobacter* adhere by means of an adhesin encoded by the *cadF* gene. Following adhesion, some species are invasive and may also express a cytolethal distending toxin and hemolysin that damage the epithelial cells. Most infections result in self-limiting diarrhea that only requires oral rehydration.

Campylobacteriosis has been linked to Guillain-Barré syndrome, where the immune system attacks the nerves causing muscle weakness and paralysis. This autoimmune disorder is believed to be caused by molecular mimicry where *Campylobacter* has *N*-acetyl neuroamine acid (sialic acid) epitopes on its surface that induce autoimmune response due to its similarity to neural gangliosides. *Campylobacter* infections have also been associated with the onset of inflammatory bowel disease (IBD), discussed below.

Salmonella enterica

The genus *Salmonella* belongs to the family Enterobacteriaceae and consists of only two species, *Salmonella enterica*, and *Salmonella bongori*. Salmonellosis in humans is caused by *S. enterica*, which has a large number of so-called serotypes or serovars and are grouped into typhoid infection caused by *S. enterica* serovar Typhi, and non-typhoid *Salmonella* (NTS) that cause gastroenteritis, respectively. The most common causes of NTS are *S. enterica* serovar Typhimurium (*S. Typhimurium*) and *S. enterica* serovar Enteritidis (*S. Enteritidis*). *Salmonella*, as well as *Campylobacter*, are frequently isolated foodborne pathogens and usually contracted from water or food contaminated with human feces. The severity of the *Salmonella* infection in humans depends on the serotype of the infective strain, and the most common clinical manifestations are enteric fever, gastroenteritis, bacteremia, and chronic carrier stage. Most of the *Salmonella* strains are capable of invading, replicate, and survive in human host cells. *Salmonella* induces phagocytosis by injecting effectors through a Type 3 Secretion System (T3SS) inside the cytoplasm of epithelial cells to trigger actin cytoskeleton rearrangements. The genes responsible for *Salmonella* invasion are found in the *Salmonella* pathogenicity islands (SPIs) located in the bacterial chromosome.

The incubation time for gastroenteric NTS infections ranges from 6 to 12 h. The infections are often self-limiting and last for a few days. A slow increase of fever (from 37°C to 41.5°C) in a couple of weeks is characteristic of the typhoid infection. This infection is associated with high morbidity and mortality in the developing world. Complications of the typhoid infection include pancreatitis, hepatitis to hemorrhages, and they have been reported in 15% of infected patients. Patients shedding bacteria in the stool for a period longer than a year are considered chronic carriers. Patients with *S. Typhi* infections are more likely to become chronic carriers than patients with NTS infection. Currently, two types of vaccines (inactive parental and oral live attenuated) are approved against the enteric fever, but no licensed vaccines are available for NTS infections (Eng et al., 2015).

Enterohemorrhagic *Escherichia coli*

Enterohemorrhagic *E. coli* (EHEC) is a subset of the *E. coli* pathotype STEC (Shiga toxigenic *E. coli*) that produce Shiga-like toxins, also known as verotoxins, due to their activity against cultured Vero cells. Like *Campylobacter* and *Salmonella*, EHEC is spread by raw or undercooked meat or contaminated vegetables and fruit. Symptoms of EHEC infection include diarrhea and abdominal pain, and sometimes fever. Cattle are considered as the main reservoirs. Once EHEC invades the human gut, it forms attaching and effacing (A/E) lesions on the mucosal epithelium (pedestal-like structures), allowing intimate contact of the bacteria with the cell followed by secretion of Shiga toxins. A total of 41 genes are involved in the formation of A/E lesions and are encoded within a pathogenicity island called locus for enterocyte effacement (LEE). The T3SS is part of the LEE and resembles a needle used to inject effector proteins into the host cells. The Shiga-like toxins Stx1 and Stx2 inhibit protein synthesis and can cause cell death, sloughing of the mucosa, inflammation, intestinal vasculitis, and, ultimately, bloody diarrhea. Most EHEC diarrheal patients recover with fluid replacement, and no further treatment is necessary (Woodward et al., 2019). In humans, EHEC may progress to a serious

life-threatening condition called HUS (Hemolytic uremic syndrome), which causes acute renal failure and anemia. Although the most studied and dangerous serotype is EHEC O157:H7, a pandemic clone capable of causing severe disease, other non-O157 EHEC strains also represent a significant public health concern.

Staphylococcus aureus

S. aureus causes a large variety of clinical infections, including bacteremia, infective endocarditis, skin infections, and soft tissue infections. It may also be present as part of the normal microbiota in the nose and skin. Studies on medical students at the Karolinska Institutet performed over nearly 10 years showed that *S. aureus* is present in the nose of one-third of the population at a given time without symptoms (Sjöling, unpublished data). *S. aureus* can also cause gastrointestinal problems, typically by food poisoning. *S. aureus* is able to grow in a range of temperatures from 7° to 48.5 °C and at a high concentration of sodium chloride (up to 15%), characteristics that favor this microorganism's ability to contaminate and grow in food during preparation and processing. During *S. aureus* growth, an assortment of enterotoxins can be produced, such as Staphylococcal enterotoxins (SEs). SEs are part of the pyrogenic toxin superantigen family, which is highly stable and heat-resistant to conditions such as freezing and drying as well as to the proteolytic activity of enzymes found in the gastrointestinal tract. The foodborne disease caused by *S. aureus* has a quick onset that takes approximately 3–5 h after ingesting contaminated food. The severity and incubation time depend on the concentration of toxin ingested. The symptoms are often immediate, including nausea, vomiting, abdominal pain, and diarrhea.

The overexposure of methicillin and β -lactam antibiotics to treat *S. aureus* infections caused the rise of methicillin-resistant *S. aureus* (MRSA) strains. MRSA strains are resistant to several antibiotics and are a serious global healthcare problem. Recently, a new strain of *S. aureus* (livestock-associated methicillin-resistant *S. aureus*, LA-MRSA) mainly found in livestock has emerged and now is considered an emerging pathogen and cause of infections in humans. In particular, LA-MRSA strains belonging to the multilocus sequence type 398 (ST398) were the most common MRSA type isolated in retail meat, and they have been found to be responsible for more than 20% of cases of MRSA. ST398 LA-MRSA have shown to have an increased capability to colonize and cause infection in human (Kadariya et al., 2014).

Public awareness and educational programs are public health interventions to prevent *S. aureus* outbreaks. Safeguarding the cold chain during food handling and preparation is crucial for preventing staphylococcal foodborne disease.

Bacillus cereus

B. cereus is a pore-forming Gram-positive microorganism well known for causing food poisoning, but also increasingly recognized as an etiological pathogen of wounds and systemic infections. Due to its capability to produce resistant endospores, *B. cereus* strains have wide dissemination in the environment, including food products, and they persist under adverse conditions, including stress-induced by pH, temperature, or nutrient deprivation. When the spores are exposed to favorable conditions (i.e., amino acids) or temperatures (>25 °C), their germination is triggered, leading to toxin production. *B. cereus* produces three different enterotoxins and one emetic toxin. The emetic toxin named cereulide is produced by cells growing in the food and results in emesis (vomiting) after ingestion, whereas the enterotoxins, which are elaborated when vegetative bacterial cells grow in the small intestine, cause diarrhea, cramps, and nausea. The three pore-forming enterotoxins Nhe (nonhemolytic enterotoxin), Hbl (hemolytic enterotoxin), and CytK (cytotoxin K), are responsible for provoking diarrhea; however, other putative virulence factors might also contribute to the diarrheal syndrome. The genes encoding the enterotoxins are located in the chromosome and broadly spread in the *B. cereus* group. The genes encoding the biosynthetic machinery for the cereulide toxin are the cereulide synthetase (*ces*) gene cluster, which is present in a 270-kb megaplasmid and limited to closely related strains. For the emetic-type illness, the onset of symptoms occurs rapidly, ranging from 30 min to 6 h after eating contaminated food. In the diarrheal type, the symptoms start after 6–15 h, typically after a meal where food was left at room temperature for several hours (Ehling-Schulz et al., 2019).

Clostridium perfringens

Clostridia are obligate anaerobic bacteria that reside in the small and large intestine and well as in soil and water. The genus includes several medically interesting species, including *Clostridium tetani* that cause tetanus, and *Clostridium botulinum* that secrete the most potent nerve toxin on earth, the botulinum toxin, commonly known as botox. Although *C. botulinum*, or its toxin, can be ingested through food and cause paralysis, this is a rare condition and will not be described in this article. The species *C. perfringens* is, however, a common cause of gastroenteritis. *C. perfringens* can give rise to serious wound infection gas gangrene characterized by large necrotic wounds and degradation of tissue. However, *C. perfringens* might also be part of the normal microbiota, and approximately 20% of humans carry the species without symptoms. But due to its ability to survive in anoxic environments and to secrete enterotoxins during sporulation, *C. perfringens* is a cause of food poisoning in food that is prepared in large batches and either transported and/or chilled and then reheated before serving. Although symptoms can be mild, elderly persons may develop severe and life-threatening diarrhea. The stress of heating and chilling may cause contaminating *C. perfringens* to sporulate and release heat stable toxins. In some cases, vegetative bacteria die during reheating leaving the toxin itself to be the only agent causing diarrhea. Prevention of anaerobic bacterial growth is taught to personnel handling food in order to abrogate outbreaks of food poisoning at hospices and schools.

Listeria monocytogenes

Infection caused by *Listeria monocytogenes* or listeriosis is a foodborne disease that affects elderly people, newborns, and immunocompromised individuals more severely. The risk is also high to pregnant women as it can lead to stillbirth or spontaneous

abortion. Typically, listeriosis causes diarrheal disease, but in risk group individuals, the pathogen can disseminate systemically, causing life-threatening sepsis or central nervous system infection. In the intestinal tract, *L. monocytogenes* can induce phagocytosis through the expression of surface proteins (internalins) encoded by two non-redundant operons, and the pore-forming toxin Listeriolysin O (LLO). LLO also contributes to the bacterial escape from the phagocytic vacuole, thus permitting *L. monocytogenes* intracellular replication. As a non-motile Gram-positive, *L. monocytogenes* induces actin biosynthesis by the host cell to propel itself through the host cell cytoplasm. Actin nucleation at one pole of the bacterium and subsequent assembly of actin filaments enables the movement of the bacterium within the cell and, eventually, its escape and invasion of a neighboring host cell.

Listeriosis is relatively uncommon, yet it has a death rate of 20–30%. Listeriosis outbreaks are associated with the consumption of food contaminated with the pathogen, typically in food-processing environments. The largest outbreak to date occurred in South Africa between June 2017 and April 2018, with 937 cases and 193 deaths (Thomas et al., 2020).

Diarrheal diseases in low-and-middle-income countries

Diarrheal diseases are a leading cause of illness and death among children under 5 years of age. Although vaccine strategies and access to clean water have improved the situation, diarrheal diseases are still estimated to cause 1.4 million deaths every year. The WHO estimates show that diarrheal diseases also rank among the top 10 causes of deaths in low income and lower-middle-income countries.

In two extensive multicenter studies, the Global Enteric Multicenter Study (GEMS) (Kotloff et al., 2013), and the Malnutrition and Enteric Disease Study (MAL-ED) (Platts-Mills et al., 2018). *Shigella* spp. together with ST toxin positive enterotoxigenic *E. coli* (ETEC) and *Campylobacter* spp. were identified as the most common bacterial causes of diarrhea in children in Africa, Asia, and Latin America. These pathogens are particularly common in young children under 2 years of age with symptoms of diarrhea and are hence serious threats to child health. Additional studies using the large material collected in these two multicenter studies, as well as follow-up studies, showed that *Shigella* and ST positive ETEC were even more common than previously thought. They were also, together with, e.g., enteropathogenic *E. coli* (EPEC) and enteroaggregative *E. coli* (EAEC), linked to death cases in children under 2 years with both severe and mild-to-moderate diarrhea.

Diarrheagenic *Escherichia coli*

Pathogenic *E. coli* encompass several well-described pathogens; two subspecies are extraintestinal, i.e., uropathogenic *E. coli* (UPEC) that cause urinary tract infections and sepsis, and neonatal meningitis causing *E. coli* (NMEC) that can cause infections of the brain as well as sepsis. These subspecies are important pathogens and implicated in the global spread of antibiotic resistance genes but are not the topic of this article, although they might be part of the gut microbiota. Intestinal pathogenic *E. coli* include the common diarrheal pathogens enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), and enteroaggregative *E. coli* (EAEC). This group is common in low-and-middle-income countries and frequent causes of diarrhea. In addition, EHEC and EIEC (enteroinvasive *E. coli*) may cause bloody diarrhea but these pathotypes seem to be less common in low-income settings.

Enterotoxigenic *Escherichia coli*

ETEC is regarded as the most common cause of tourist's diarrhea. It is contracted by the ingestion of contaminated food and drink and give rise to a range of mild symptoms of diarrhea to profuse watery diarrhea that resembles severe cholera. Vomiting and fever are sometimes associated with ETEC diarrhea. ETEC colonizes the distal ileum and adheres to the epithelium by means of colonization factors (CFs) termed CFA/I and CS1-CS8, CS12-14, CS17-23, CS26-31. Each isolate typically expresses 1-3 CFs and one or two toxins. The toxins give rise to watery diarrhea and secretion of Na⁺ and Cl⁻ characteristic of ETEC diarrhea and cholera. The A-B toxin heat-labile toxin (LT) is homologous to the cholera toxin (CT) and binds GM1 on the epithelial surface. It activates adenylate cyclase and increases cAMP in the cell, causing deregulation and opening of the ion channel cystic fibrosis transmembrane regulator (CFTR). The other toxin type of ETEC is the heat-stable toxin with the two variants STh and STp commonly found in human isolates. ST toxins are small peptides that increase intracellular cGMP and also open the CFTR. While large studies repeatedly linked ST positive ETEC with diarrheal cases, ETEC strains expressing only-LT are found both in asymptomatic and symptomatic carriers.

Enteropathogenic *Escherichia coli*

EPEC is another major pathogen infecting children and a frequent cause of persistent diarrhea. EPEC can be divided into two groups: typical EPEC (tEPEC) or atypical EPEC (aEPEC) strains. Typical EPEC strains express virulence genes *eae* (involved in an AE phenotype similar to EHEC) and *bfp* (bundle forming pili) but lack Shiga toxin genes found in STEC. Atypical EPEC are *eae* positive and *bfp* and *stx* negative. EPEC attach to the small and large intestine through Bfp, promoting microcolony formation. As EHEC, EPEC injects virulence factors encoded by the LEE region and the EAF plasmid into the host cell via the T3SS and form AE lesions. During adherence, tEPEC strains are able to display a localized adherence pattern, while aEPEC strains have more diverse patterns (diffuse, aggregative, or localized). The major reservoir of tEAEC are humans, but aEPEC can be found in both animals and humans. The GEMS reported that tEPEC is not a leading pathogen associated with moderate to severe diarrhea in children; however, EPEC remains an important etiological agent in some countries of the developing world and is the most frequent pathogen detected in mixed infections. Other studies have shown significant proportions of EPEC, specially aEPEC, in asymptomatic cases. tEPEC cause secretory diarrhea with significant water discharges and mucus. EPEC infection can also trigger severe malabsorption of nutrients

that can result in nutritional aggravation and persistence of diarrhea. Some aEPEC strains have the serotype O55:H7 and share virulence and genetic features with EHEC O157:H7. Atypical EPEC might be precursors for *stx*-positive isolates. For example, one study showed that the aEPEC O103:H25 infected by the *stx* bacteriophage became STEC with increased virulence (Sekse et al., 2008).

Enteraggregative *Escherichia coli*

EAEC is a heterogeneous emerging pathogen that causes acute and persistent diarrhea (more than 14 days) among infants. EAEC is also an important pathogen associated with travelers' diarrhea and outbreaks in industrialized countries. EAEC has a distinct ability to produce a "stacked-brick" adherence pattern on epithelial cell lines. To cause infection, EAEC first employs several adhesins (aggregative adhesion fimbria, AAF/I to AAF/IV) to attach to enterocytes and form a biofilm. EAEC also secrete enterotoxins (i.e., EAST1S, SHET1, and pic) and cytotoxins (pet) that cause secretion of electrolytes and inflammation of the mucosa. EAEC is able to disperse along the intestinal mucosa through the secretion of an anti-aggregation protein called dispersin, which helps to establish new infection sites. A large number of EAEC virulence factors are regulated by the transcriptional factor AggR—that controls the expression of 44 plasmid and chromosome-borne virulence genes.

EAEC infection can be characterized by the presence of watery diarrhea and sporadically mucoid diarrhea. Children that have reported EAEC infection suffered from growth impairment regardless of the presence of diarrhea. Most of the studies in the developing world have associated EAEC with diarrhea, but others have also found EAEC in an equal number from cases and control individuals. Acquired immunity as a consequence of frequent exposure to this pathogen where poor sanitation is prevalent, as well as the circulation of strains with low pathogenicity, can be the explanation of asymptomatic carriers of EAEC. The broad diversity in virulence genes makes the establishment of international surveillance and therapeutic approaches challenging (Jensen et al., 2014).

Vibrio cholerae and other *Vibrio* spp.

Vibrio cholerae is a Gram-negative, single-flagellated, and highly motile bacterium native to estuarine and marine environments worldwide. The species includes harmless strains as well as strains that have been responsible for epidemic and pandemic cholera disease. Virulent strains contain the CTX ϕ bacteriophage that encodes the cholera toxin.

Environmental persistence of *V. cholerae* is facilitated by bacterial attachment and biofilm formation to abiotic and biotic surfaces, including chitinous organisms that provide chitin as a carbon source facilitated by the bacterium's chitinase activity. *V. cholerae* has a complex lifestyle that includes viable but non-culturable (VBNC) cells, predominantly found within the bacterioplankton, and culturable cells, predominantly found as aggregates or as part of biofilms. Environmental conditions such as temperature and nutrient availability induce the switch from VBNC to culturable (Lutz et al., 2013).

V. cholerae survives the action of bile salts and host antimicrobial peptides through the secretion of outer membrane vesicles. During infection, it secretes the cholera toxin (CT), composed by an A subunit and five B subunits. Toxin-coregulated pili contribute to the bacterial attachment to intestinal epithelial cells. The CT B subunit binds to GM1 gangliosides on the surface of intestinal epithelial cells, inducing endocytosis of the toxin and the release of the A subunit, leading to increased adenylate cyclase activity and the secretion of water and electrolytes to the intestinal lumen that can cause profuse, watery diarrhea. Two serogroups, O1 and O139, have been responsible for seven pandemics between 1817 and 1971. Most infections are asymptomatic or mild. The Centers for Disease Control (CDC) estimates that only 5–10% of the carriers develop severe disease. Estimations calculate 1.3–4.0 million cases per year, causing 21,000–143,000 deaths, primarily in South Asia, Africa, and areas of Latin America. Treatment includes rehydration therapy, antibiotic administration, and in pediatric cases, zinc supplementation. In 2016, the FDA approved an oral vaccine against cholera.

Non-cholera *Vibrio* spp. like *Vibrio vulnificus* or *Vibrio parahaemolyticus* are causative agents of vibriosis, a less severe diarrheal disease than cholera associated with the consumption of contaminated raw seafood. Vibriosis is not restricted to the developing world and is responsible for over 80,000 cases of infections every year only in the US, according to the CDC.

Shigella spp.

Dysentery or shigellosis caused by the invasion of the intestinal epithelium by *Shigella* spp. in the terminal ileum, colon, and rectum, manifests as bloody diarrhea and was described for the first time over 100 years ago. It only affects primates, including humans. Pathogenic *Shigella* are classified into four major serological groups: Group A (*Shigella dysenteriae*), Group B (*Shigella flexneri*), Group C (*Shigella boydii*), and Group D (*Shigella sonnei*). Disease caused by *S. sonnei*, which is prevalent in the developed world, tends to be mild. The most severe manifestation of the disease is caused by *S. flexneri*. A hallmark of shigellosis is the low infective dose needed, which can be as low as 10 microorganisms for some virulent strains (Kothary and Babu, 2001).

Shigella infection requires a conserved T3SS encoded on a large plasmid common to all *Shigella* spp. Upon transcytosis to the epithelial sub-mucosa through M cells, *Shigella* spp. are phagocytosed by macrophages, but a swift induction of apoptosis enables bacterial survival and spread. Destruction of the epithelial lining occurs upon recruitment and infiltration of polymorphonuclear neutrophil leukocytes, originating bloody diarrhea typical of the disease. Some strains produce the Shiga toxin, which inhibits protein biosynthesis by targeting the 28S rRNA of the 60S ribosomal subunit. *Shigella* infections are endemic to temperate and tropical regions and are estimated 80–165 million annually, causing 600,000 deaths.

Yersinia enterocolitica

Yersinia enterocolitica is the causative agent of yersiniosis, causing enteritis, including fever and sometimes bloody diarrhea, especially in children. Domestic pigs constitute the main reservoir of *Y. enterocolitica*. Thus, consumption of infected undercooked pork is usually the cause of infection, although outbreaks associated with consumption of vegetables or contaminated water have also been reported. Pathogenic *Yersinia* spp. harbor a virulence plasmid named pYV that encodes a T3SS called the Ysc injectisome, as well as proteins secreted by Ysc, collectively termed “Yops” (*Yersinia* outer proteins). Expression of the genes encoding the Ysc-Yop system depends on the AraC-family transcriptional activator VirF, whose expression is controlled by temperature, and contributes to bacterial survival to host defenses by arresting phagocytosis (Shoaib et al., 2019). *Y. enterocolitica* is unable to chelate iron and relies on siderophores produced by other bacteria to acquire this element. Variants of pYV harbor a high pathogenicity island encoding the siderophore yersiniabactin that contributes to bacterial virulence (Pelludat et al., 2003). Indeed, iron supplementation is associated with higher severity of the disease. *Y. enterocolitica* also harbors a chromosomally encoded heat-stable enterotoxin similar to that of ETEC, although its contribution to infection is thought to be minor. The CDC estimates more than 100,000 annual cases of yersiniosis only in the US every year.

Gastric infections

In the stomach, ingested food is blended with highly acidic gastric juice. The luminal content of the stomach is hence acidic and typically ranges from pH 1–5. This environment was considered to be too hostile for bacterial colonization until the discovery of *Helicobacter pylori* in 1983. This finding by Barry J. Marshall and J. Robin Warren was later rewarded with the Nobel prize in Physiology or Medicine in 2005.

Helicobacter pylori

H. pylori is a Gram-negative, microaerophilic bacterium that thrives in the gastric epithelium and lumen, where oxygen levels are around 5%. *H. pylori* is not an acidophilic bacterium but uses the action of secreted urease to neutralize the surrounding acidic environment. *H. pylori* adheres to the gastric epithelium by means of the adhesion factors BabA and SabA and secretes the major toxins CagA and VacA. CagA induces cell rearrangements and alters signaling cascades, while VacA induces apoptosis and formation of vacuoles in the target cell.

H. pylori infection is common, and it is estimated that half of the world’s population is infected. Infection is more common in low socioeconomic populations where up to 90% can be infected. Although infection always causes inflammation of the gastric epithelium, the majority of the infections do not give symptoms. However, 10–15% of cases develop gastric or duodenal ulcers and 1–2% gastric cancer.

H. pylori entirely dominates the stomach microbiota in persons with ongoing *H. pylori* infection. Sequence analyzes often record more than 90% of the total content to be *Helicobacter*. However, other species might be found in the healthy stomach; the absolute numbers of bacteria are much lower, and many species are probably transient bacteria that do not reside permanently in the stomach mucosa. Lactobacilli and oral species such as *Streptococcus*, *Veillonella*, and *Treponema* are often found in the stomach both in the presence and absence of *H. pylori*.

Emerging pathogens

Improvements in bacterial identification methods, boosted by next-generation sequencing technologies and microbiome studies, have expanded the spectrum of species associated with human gastrointestinal disease. One of the most renowned cases is that of *Fusobacterium nucleatum*, a commensal bacterium and strict anaerobe that colonizes the oral cavity that is rarely isolated from extra-oral samples in healthy individuals. There is, however, a growing body of evidence that shows an association between *F. nucleatum* abundance and gastrointestinal diseases like inflammatory bowel disease (IBD), colorectal cancer (CC), or appendicitis (Allen-Vercor et al., 2011). There is currently no clear evidence of whether *F. nucleatum* is an opportunistic colonizer, perhaps facilitated by disease-induced dysbiosis upon translocation from the oral cavity, or an active driver of disease.

Waterborne bacteria are frequent causative agents of gastrointestinal disease, normally after exposure to water or consumption of raw fish or seafood. In recent years, occasional reports *Shewanella algae* gastrointestinal infection have been published. Microbiome studies have detected an increased abundance of *Shewanella* spp. in colorectal cancer mucosa (Flemer et al., 2017; Kinross et al., 2017). The role of *Shewanella* spp., if any, in gastrointestinal disease remains unclear. Other waterborne bacteria reported causing human GI infection include members of the genera *Aeromonas* and *Plesiomonas* (Vila et al., 2003).

Development of Crohn’s disease (CD) has been linked to exposure to *Mycobacterium avium* subspecies *paratuberculosis* (MAP), an intracellular bacterium that is transmitted to humans primarily through milk consumption or upon contact with the pathogen in the environment (McNees et al., 2015). As with other potential emerging pathogens, further research is needed to prove it as a causative agent of CD.

Bacterial dysbiosis

Bacterial dysbiosis is a disturbed composition of bacterial species residing at a specific location. There is an increasing recognition that a highly diverse consortium of bacterial species in the GI tract is beneficial for health. Hence, when the balance is disturbed by an overgrowth of individual species or shifts towards specific members of the gut microbiota with certain metabolic properties, disease symptoms might occur.

Inflammatory diseases of the GI tract

Inflammatory bowel disease

IBD is characterized by chronic inflammation of the GI tract with alternating clinical relapse phases and remissions. IBD is divided into ulcerative colitis (UC) and Crohn's disease (CD). IBD is believed to be an overreaction of the immune system towards the resident microbiota, and although genetic predisposition, environmental factors, and composition of the microbiota seem to play a role, the factors behind the onset of UC and CD are not fully known. The mucosa of IBD patients is inflamed, and high levels of pro-inflammatory cytokines such as TNF α and IL-6 are secreted by activated immune cells. Hence, e.g., anti-TNF therapy has proven to help a subset of patients. Recent studies indicate that analyzes of the composition of the microbiota might be able to predict if anti-TNF treatment is successful or not in IBD patients.

Inflammatory bowel symptoms

IBS is a common condition characterized by disturbed bowel functions. The symptoms are diffuse and include abdominal pain, bloating, and dysfunctional bowel habits, including diarrhea and constipation. It has been estimated that 6–10% of the general population suffer from IBS. Several studies have indicated that a change in diet might improve IBS. The FODMAP regime that include a diet low in fermentable oligosaccharides, di- and monosaccharides, and polyols has been successful for some IBS patients. Several studies suggest that the resident microbiota composition can play a role in whether the patient improves by the diet or not.

Acute GI infections have been linked to later development of persistent symptoms such as induction of IBD and IBS. A systematic review identified *Salmonella*, *Campylobacter*, and *Clostridioides difficile* to be associated with increased risk of incident IBD (Axelrad et al., 2020). Increasing evidence have associated the *E. coli* pathobiont (neither commensal nor a true pathogen) adherent-invasive *E. coli* (AIEC) with Crohn's disease (CD). AIEC has also been found in healthy volunteers, and no virulence marker has been described yet in comparison to the other well-characterized pathotypes of *E. coli*. However, it can cause perturbations in the normal intestinal environment and due to the presence of some genetic determinants such as adhesins and invasins, allow the bacteria to invade the intestine, expand and exacerbate inflammation (Shaler et al., 2019).

Clostridioides difficile

The normal microbiota often contains low numbers of *Clostridioides difficile* (formerly *Clostridium difficile*). *C. difficile* is associated with a common type of bacterial dysbiosis caused by the use of broad-spectrum antibiotics that kill several species and allow expansion of resistant *C. difficile*. The resulting so-called antibiotic-induced diarrhea is a common nosocomial infection and can be life-threatening if it develops to pseudomembranous colitis. The overgrowth of *C. difficile* cause severe inflammation of the large bowel due to the action of two toxins A and B (TcdA and TcdB). As in many other pathogens, there are increasing concerns over the occurrence of hypervirulent clones. In *C. difficile* the ribotype 027 emerged in 2003 and has since then spread globally. It is responsible for outbreaks globally and produces more toxins, have increased adherence to the epithelium and is resistant towards fluoroquinolones and erythromycin. Other emerging clones are ribotype 078 and 106, where the latter has increased in recent years.

Since the cause of CDI often is antibiotic treatment, it is imperative to stop administration of the first antibiotics. Thereafter treatment with vancomycin or metronidazole, effective towards anaerobes like *C. difficile*, is often the next therapy. Some CDIs are cured by this second administration of antibiotics, but recurrent diarrhea occurs in a subset of patients. Fecal microbiota transplants (FMT) is an effective therapy for CDI. Although the exact mechanisms that confer mitigation of the CDI diarrheal symptoms are unknown, it is believed that the transferred FMT contains a healthy gut microbiota that establishes itself in the recipient and restores normal gut functions.

There are some indications that the metabolites of the FMT are responsible for the cure of treated patients. The primary bile taurocholic acid (TCA) promote spore germination of *C. difficile*, whereas secondary bile acids like deoxycholic acid inhibit vegetative growth and toxin activity. In humans, primary bile acids secreted by the gall bladder into the duodenum are converted by large bowel resident microbiota species expressing bile salt hydrolases and bile converting enzymes (i.e., 7- α -dehydroxylase). In support of this CDI, patients have been found to have low levels of secondary bile acids and higher levels of TCA, which would support active growth and toxin production in CDI patients. Other gut factors of importance are short-chain fatty acids (SCFA). Short-chain fatty acids, particularly acetate, propionate, and butyrate, are produced by resident microbiota, and lower levels of SCFA are found in CDI patients. It is, however, unclear if this is a consequence of antibiotic treatment. Valerate, a five-carbon SCFA, seems to inhibit the growth of *C. difficile*, which supports the role of SCFA.

Colonization mechanisms in the intestinal tract

The GI tract is normally colonized by bacterial species of the phyla Firmicutes and Bacteroidetes, while Actinobacteria, Verrucomicrobia, and Proteobacteria are present at lower levels. These phyla cover over 1000 species that normally live in the GI tract and constitute the normal microbiota. The presence of this vast number of different species provides so-called colonization resistance (CR) to invading pathogens by competing for nutrients and space. CR is often very efficient, but some pathogenic species elaborate intriguing mechanisms to overcome this. The ability of pathogenic species to outcompete the normal microbiota is a new research field with interesting findings.

Several pathogens utilize specific host factors present in the GI tract to induce virulence genes encoding adhesion factors and toxins that facilitate inflammation and disease progression. In addition, certain pathogenic members of, e.g., Proteobacteria, have the ability to outcompete the resident microbiota, and reports have shown that, e.g., *V. cholerae*, *S. Typhimurium*, and ETEC can constitute over 50% of all bacteria in the gut during acute diarrheal sequelae. There is evidence that this overgrowth is due to an inherent ability to cause inflammation of the epithelium, followed by the specific use of competing nutrients or alternative metabolic pathways in the inflamed gut. Pathogenic bacteria are able to adapt to and survive the gastrointestinal tract and cause symptoms by adherence to the epithelium. While some bacteria like *Salmonella enterica* and *Shigella* spp. induce massive inflammation and/or invasion others like *V. cholerae*, and ETEC are believed to cause only mild inflammation and instead induce diarrheal symptoms by cytotoxic toxins that deregulate electrolyte and water secretion of epithelial cells. Regardless, the onset of both mild and severe inflammation might release new factors into the gastrointestinal tract, and pathogens that can use these for metabolism have an advantage over resident microbiota that cannot metabolize the specific factors.

Interactions with host factors that facilitate colonization and virulence

Mucin degradation

The surface of the GI epithelium is covered by a layer of mucus (mucin), whose composition, structure, and thickness varies along the GI tract. This protective layer prevents epithelial cells from damage caused by harsh substances, and at the same time, acts as a barrier against pathogens. A major component of mucin is O-glycans, which constitute a carbon source for the associated microbiota, thus offering a complex niche whose microbial composition varies longitudinally and transversally in the GI (Tailford et al., 2015). The inner layer of mucin, closer to the epithelial lining, is reported to be sterile (Hansson and Johansson, 2010).

The ability to degrade mucin is a fitness advantage for several gut pathogens, not only for its utilization as a carbon source but also as a way to gain access to host cells. Mucinase activity has been demonstrated for *Shigella flexneri*, *Helicobacter pylori*, pathogenic *E. coli*, and *V. cholerae*, among other pathogens (Carlson-Banning and Sperandio, 2016). The diverse O-glycan composition of mucin also provides a primary attachment point for GI pathogens. *S. enterica*, for example, while unable to degrade complex glycans, attaches to intestinal glycans and uses monosaccharides released upon mucin degradation by the commensal consortium (Josenhans et al., 2020). Expression of mucin-binding adhesins and lectins is thus included in the 'toolbox' of an array of pathogens, including *S. enterica*, *C. jejuni*, EHEC, *V. cholerae*, and *L. monocytogenes*.

Bile salt tolerance

Pathogenic bacteria that aim to colonize the human gut have to encounter the antimicrobial detergent-like activity of bile acids, which are secreted upon digestion. In addition to the physiological roles of bile, enteric pathogens have evolved to tolerate and use bile acids as signal molecules for the activation of virulence. For example, bile acids activate the expression of virulence genes of ETEC involved in adherence but inhibit toxin production (Joffe et al., 2019). In *Shigella flexneri*, bile induces over 50 genes, many of them involved in colonization and T3SS effectors. Bile acids also activate several pathogenic features of *V. cholerae*, including biofilm formation, T3SS, T6SS, and virulence regulation. *Salmonella* has shown to be more tolerant to bile acids, which is achieved by pumping out the bile acids and modifying the lipopolysaccharides of the outer membrane for increased fitness in a bile-rich environment. Among Gram-positive pathogens, bile acids can be crucial for *C. difficile* infection by interacting with the germinant receptors within the spores' inner membrane that trigger spore germination (Sorg and Sonenshein, 2008). Overall, these and more other examples highlight that bacterial pathogens can respond to their environmental surroundings to effectively regulate the virulence to successfully cause infection (Sistrunk et al., 2016).

Utilization of local or host-derived oxygen and anaerobic electron acceptors

A signature of gut inflammation is an unbalanced proportion of strict anaerobes with respect to Proteobacteria, including Enterobacteriaceae, a phenomenon that is at least in part driven by oxidation of formate and respiration of oxygen in vivo as shown in a murine model of colitis (Hughes et al., 2017). Inflammation induces oxygenation after increased blood flow, and aerobic metabolism is thus a key factor in the establishment and overgrowth of facultative anaerobic pathogens, including, e.g., *V. cholerae* (Van Alst and DiRita, 2020). Oxygen levels in the small intestine are higher in intestinal crypts than in the lumen and the tip of villi, where the microenvironment is nearly anoxic. Hence, the observed requirement of oxygen for colonization and/or virulence of pathogenic facultative anaerobic bacteria infecting the small intestine, including ETEC and *V. cholerae*, might indicate that intestinal crypts are the main site of infection for these pathogens.

While aerobic metabolism is the most energetically favorable, the intestinal tract provides niches that are rich in other substances that can fuel bacterial anaerobic metabolism. During *Salmonella* infection, inflammation of intestinal tissues generates reactive oxygen species that react with local thiosulfate to form tetrathionate, a compound that *Salmonella* can use as an electron acceptor for anaerobic respiration and whose utilization gives a growth advantage to the pathogen (Winter et al., 2010). In vivo oxidation of trimethylamine generates trimethylamine N-oxide (TMAO), a compound that also forms part of the repertoire of alternative electron acceptors used by *Salmonella* or *E. coli*. Nitrate, a major alternative electron acceptor, used by many facultative anaerobes, has been shown to be generated in situ in the gut during inflammation and used by commensal *E. coli* to colonize the intestines in a mouse model (Winter et al., 2013). The genome of *E. coli* encodes two respiratory and one dissimilatory nitrate reductases, which are conserved across pathotypes; therefore, it is reasonable to assume that such a capacity could also be used by pathogenic *E. coli* strains to thrive during infection. Taken together, this exemplifies how a versatile facultative metabolism, together with swift adaptation of cellular programs to changing tissue environments, contribute to pathogen spread and disease progression.

Summary

In summary, bacterial gastroenteric diseases and/or symptoms are caused by interactions between a diverse set of pathogenic bacteria and the human host. The ability of these bacteria to cause disease in humans seems to be dependent on the ability to sense host factors and interact with, and utilize, the resident microbiota as well as the gut epithelium. It is evident that we still need to understand much more how pathogens use environmental factors and other species to be able to colonize the hostile environment that constitutes the gastrointestinal tract in order to be able to prevent or fight gastrointestinal diseases more efficiently. This is important since gastrointestinal diseases still are significant causes of global morbidity and mortality.

Introduction

Diarrheal diseases are a leading cause of morbidity worldwide, particularly among young children (Global Burden of Disease (GBD) 2019 Diseases and Injuries Collaborators, 2020). An estimated 4.5 billion episodes of diarrhea and >1.5 million diarrhea-related deaths occur annually, with the highest burden in the youngest and oldest age groups (Global Burden of Disease (GBD) Collaborators, 2017a,b; Global Burden of Disease (GBD) 2016 Disease and Injury Incidence and Prevalence Collaborators, 2017). Viral etiologies of diarrheal illnesses are common: it has been estimated that 3 of the top 10 causes of pediatric diarrheal deaths are due to illnesses caused by viruses (Global Burden of Disease (GBD) Collaborators, 2017b).

Major viral etiologies of diarrheal disease include rotavirus, norovirus, sapovirus, astrovirus, and enteric adenoviruses (Fig. 1) (Global Burden of Disease (GBD) Collaborators, 2017b). Among these pathogens, rotavirus group A (RVA) is associated with the greatest morbidity and mortality burden, concentrated among young children <5 years of age (Global Burden of Disease (GBD) Collaborators, 2018). Although RVA burden has been declining due to increasing implementation of national vaccination programs, RVA remains a leading cause of severe pediatric diarrheal illness and deaths, especially in lower-resource countries (Global Burden of Disease (GBD) Collaborators, 2018). Adenovirus has been estimated to cause the next highest numbers of diarrheal episodes and deaths, also disproportionately affecting children <5 years (Global Burden of Disease (GBD) Collaborators, 2018; Lee et al., 2020). Although norovirus commonly causes illness across the age spectrum (Burke et al., 2021; de Wit et al., 2001; Harris et al., 2017; Kirk et al., 2015; O'Brien et al., 2016), it is an increasingly prevalent etiology of pediatric diarrhea in settings with high coverage of RVA vaccine (Hassan et al., 2019; Koo et al., 2013; Lartey et al., 2020; McAtee et al., 2016; Payne et al., 2013). Astrovirus and sapovirus, while not as prevalent as RVA, norovirus, or adenovirus, also contribute to the burden of viral gastroenteritis, especially among young children (Burke et al., 2021; Mattison et al., 2021; Vielot et al., 2021). This chapter will discuss molecular, immunological, and epidemiological aspects of each of these five enteric viruses, including methods of diagnosis, prevention, and control.

Clinical presentation and management

Viral gastroenteritis commonly causes sudden-onset diarrhea, vomiting, abdominal pain, and fever. Although illnesses are usually self-limiting, symptoms can be severe, leading in some cases to dangerous dehydration; severe outcomes, such as hospitalization and death, are more common in lower-resource settings, as well as among young children and older adults (Global Burden of Disease (GBD) Collaborators, 2017a). There are no specific treatments for viral gastroenteritis: clinical management focuses on

Fig. 1 Electron micrographs of negatively strained gastroenteritis viruses. Bar = 100 nm. Courtesy: Charles Humphrey, CDC.

prevention of or treatment for dehydration or through oral or, in severe cases, intravenous rehydration (Banyai et al., 2018; Hartman et al., 2019). Antiemetics and probiotics are sometimes used as adjunct therapies, and may help reduce duration of symptoms, although more evidence is needed to recommend universal use (Collinson et al., 2020; Hartman et al., 2019). Antimotility drugs are not recommended for treatment of acute gastroenteritis (AGE) in young children (Banyai et al., 2018; Hartman et al., 2019).

Enteric viruses are transmitted through the fecal-oral route, making sanitation and hygiene key elements of prevention and control. Handwashing with soap and water is especially important for norovirus, as alcohol-based hand cleaners have been shown to be less effective against norovirus (Liu et al., 2010; Tuladhar et al., 2015). Additionally, many enteric viruses, particularly norovirus, can be environmentally persistent (Espinosa et al., 2008; Kotwal and Cannon, 2014); thus, surface cleaning with effective disinfectants is an important part of halting onward transmission. Because the infectious dose for some enteric viruses is quite low, and prolonged fecal shedding can be common, it is recommended that sick individuals exclude themselves from food preparation and some types of work (e.g., work in a healthcare setting) for at least 48 h following symptom resolution (Banyai et al., 2018). Among the five viruses discussed in this chapter, only RVA has licensed vaccines available, although several norovirus candidate vaccines are in development (Mattison et al., 2018; Burke et al., 2019; Cates et al., 2020).

Rotavirus

History

Rotaviruses were first described in diarrheic mice (Adams and Kraft, 1963), monkeys (Malherbe and Harwin, 1963) and cattle (Mebus et al., 1969) in the 1960s. The first human-associated RVA was discovered in 1973 by electron microscopy (EM) in duodenal biopsy samples from children with severe diarrhea and in diarrheic fecal samples from children (Bishop et al., 1973; Flewett et al., 1973). Rotavirus is derived from the Latin word *rota* (meaning wheel), for its wheel-like appearance (Estes and Greenberg, 2013; Flewett et al., 1974).

Morphology

RVAs are nonenveloped, icosahedral-shaped viruses as observed by negative-stain EM (Fig. 1). Three types of RVA particles are observed under EM: (1) triple-layered particles (TLP) composed of a 3-capsid structure: an inner core, an intermediate capsid, and an outer capsid with short radiating spikes; (2) double-layered particles lacking an outer capsid; and (3) single-layered particles lacking outer and intermediate capsids (Crawford et al., 2017; Estes and Kapikian, 2007). TLP are ~100 nm in diameter and are considered infectious (McClain et al., 2010).

Structure

RVAs possess a genome of 11 double-stranded RNA (dsRNA) segments. Six segments encode genes for structural proteins (VP1, VP2, VP3, VP4, VP6, and VP7), and five encode non-structural proteins (NSP1, NSP2, NSP3, NSP4, NSP5/NSP6) (Estes and Kapikian, 2007; McClain et al., 2010; Estes and Greenberg, 2013). Each segment encodes a single protein except for segment 11, which can encode for two non-structural proteins, NSP5 and NSP6, in some strains. The 11 dsRNA segments are surrounded by the VP2 protein, which forms the inner capsid, and the VP6 protein that forms the intermediate capsid. The outer capsid is comprised of the VP7 protein, which forms the shell around the virion (Aoki et al., 2009), and the VP4 protein, which forms the protease-activated spikes that protrude outward from the capsid for attachment (Dormitzer et al., 2002) (Fig. 2A).

Disease Primers* 3: 17083.

Nomenclature

Rotaviruses belong to the family *Reoviridae* with at least 10 distinct groups (A–J) based on the antigenic properties of VP6 gene (Matthijnssens et al., 2012). RVA causes >90% of human infections, although rotavirus group B (RVB) and rotavirus group C (RVC) are also associated with AGE. RVA can be classified into 2 major genome patterns: long or short RNA profiles or electropherotypes [E-type], based on differences in the relative migration pattern of genome segments 10 and 11 on polyacrylamide gels (Fig. 2B). Two outer capsid proteins are used traditionally to classify RVA: VP7 determines the G (glycoprotein) serotypes/genotypes, and VP4 determines the P (protease-cleaved) serotype/genotype. Since 2008, a classification scheme based on nucleotide sequence identity cutoff percentages has been used to assign a genotype to each of the 11 RVA genes: Gx-P[x]-Ix-Rx-Cx-Mx-Ax-Nx-Tx-Ex-Hx for VP7-VP4-VP6-VP1-VP2-VP3-NSP1-NSP2-NSP3-NSP4-NSP5/6 (Matthijnssens et al., 2008). To date, RVAs of human and animals have been classified into at least 36 G, 51 P, 26 I, 22 R, 20C, 20 M, 31 A, 22 N, 22 T, 27 E, and 22 H genotypes (Table 1) (Banyai et al., 2018). Currently, >80 G and P genotype combinations of RVA are known to infect humans, but six combinations (G1P[8], G2P[4], G3P[8], G4P[8], G9P[8], and G12P[8]) account for about 90% of severe infections (Banyai et al., 2018).

Replication and specific aspects of infection

RVA enters the body through the mouth and infects the mature enterocytes on the tips of the absorptive intestinal villi of the small intestine (Ramig, 2004). The incubation period of RVA in young children is 1–3 days (Bishop, 1996) and symptoms typically last 3–7 days, although in more severe cases symptoms can last up to 14 days (Bernstein, 2009). RVA infection is usually localized to the intestinal tract; however, antigenemia and viremia have been reported in children with RVA diarrhea (Blutt et al., 2003; Moon et al., 2012).

RVA entry into host cells is a multistep process. Both outer-capsid proteins VP7 and VP4 play important roles in virus entry and infection (Crawford et al., 2017). After infection, the VP4 protein is cleaved by intestinal trypsin into two polypeptides: VP8*, which forms the head of the protein, and VP5*, which forms the stalk and base of the protein (Arias et al., 1996). The VP8* domain of the RVA VP4 protein mediates initial interaction with the host cell surface, followed by the interactions of RVA proteins VP5* and VP7 with multiple co-receptors (Arias et al., 1996; Lopez and Arias, 2004; Desselberger, 2014). RVA attachment to host cells is also mediated by binding partners on the host cell surface, including sialoglycans and human histo-blood group antigens (HBGAs), carbohydrates found on the surface of gut epithelial cells (Arias et al., 2015). Following entry, RVA travel to different endosomal compartments and lose their outer layer before entering the cytosolic space (Arias et al., 2015). After cellular uptake, RVA replication and assembly occur in cytoplasmic viroplasms, and newly produced RVA are released from the cells through cell lysis or vesicular transport (Fig. 3) (Crawford et al., 2017).

Table 1 Rotavirus group A (RVA) genes and genotypes.

Gene segment	Encoded protein	Size in bp	Location in virus particles	Protein	Protein function	Number of genotypes	% Identity cutoff
1	VP1	3302	Core	RNA-dependent RNA polymerase	Complex with VP3	22R	83
2	VP2	2687	Core	Inner capsid core protein	Required for replicase activity of VP1	19C	84
3	VP3	2592	Core	Methyltransferase	Complex with VP1	20M	81
4	VP4	2362	Outer Capsid	Protease-sensitive outer capsid protein, P-type neutralization antigen	Attachment protein, protease-enhanced infectivity, virulence, fusion with cell membrane	51P	80
5	NSP1	1581	Nonstructural	Interferon antagonist	RNA binding, E3 ligase	31A	79
6	VP6	1356	Inner Capsid	Intermediate capsid protein	Intracellular neutralization, required for transcription	26I	85
7	NSP3	1074	Nonstructural	Translation enhancer	Inhibits host protein translation	22 T	85
8	NSP2	1059	Nonstructural	NTPase	Inhibits host protein translation	22 N	85
9	VP7	1062	Outer Capsid	Glycoprotein, G-type neutralization antigen	Glycoprotein calcium-dependent trimer	36G	80
10	NSP4	751	Nonstructural	Enterotoxin	Plays role in morphogenesis of TLPs, interacts with viroplasms and modulates intracellular calcium and RNA replication	27E	85
11	NSP5	666	Nonstructural	Phosphoprotein	Essential for viroplasm formation, RNA binding, interaction with VP2 and NSP6	22H	91
	NSP6		Nonstructural		Interaction with NSP5, localization in viroplasms		

Modified from Desselberger U (2014) Rotaviruses. *Virus Research* 190: 75–96.

Fig. 3 The rotavirus group A (RVA) replication cycle. (A) RVAs attach to different glycan receptors on the host cell surface through interaction with the viral protein 8* (VP8*) domain of VP4. (B) The virus is internalized into cells by endocytic pathways. The low calcium levels inside the endosome trigger the removal of the outer capsid layer, which releases the transcriptionally active double-layered particle (DLP) into the cytoplasm. (C) Viral mRNA is used as a template for RNA synthesis during genome replication; the RNA is then packaged into new DLPs within viroplasm. (D) Triple-layered particle assembly involves the binding of newly formed DLPs to non-structural protein 4 (NSP4), which serves as an intracellular receptor, followed by the budding of DLPs into the endoplasmic reticulum (ER). (E) In the ER, transient enveloped particles can be observed and the outer capsid proteins VP4 and VP7 are added onto the DLPs. The envelope is then lost, the virus particles mature, and progeny virions are released from cells through cell lysis or by a Golgi-independent non-classical vesicular transport mechanism in polarized epithelial cells. Used with permission from Crawford SE, Ramani S, Tate JE, Parashar UD, Svensson L, Hagbom M, Franco MA, Greenberg HB, O’Ryan M, Kang G, Desselberger U and Estes MK (2017) Rotavirus infection. *Nature Reviews. Disease Primers* 3: 17083.

Immunity

Natural infection with RVA reduces the frequency of subsequent RVA episodes, and specifically protects against subsequent RVA AGE. Acquired immunity is important to prevent both recurrent disease and, to a lesser extent, reinfection following primary infection (Velazquez et al., 1996). The first level of immunity to human RVA is an innate susceptibility or resistance to infection based partially on an individual’s HBGAs phenotypes expressed on the gut surface epithelium. The ABO blood group, fucosyltransferase 2 (FUT2), and fucosyltransferase 3 (FUT3) genes define the ABO blood group antigens, secretor/nonsecretor, and Lewis antigen phenotypes, respectively, of HBGAs, which function as binding ligands and initial receptors required for RVA binding to host cells (Banyai et al., 2018) (Loureiro Tonini et al., 2020). Binding of the VP4 surface protein to the HBGAs occurs in a genotype-dependent manner, suggesting that HBGAs are putative receptors for RVA binding (Huang et al., 2012). The distribution of HBGAs types in different human populations is thought to affect the prevalence of common RVA genotypes across the globe, as well as susceptibility to some strains of animal origin (Nordgren et al., 2014).

RVA immunity is multifactorial, achieved through the combined action of secretory antibodies and humoral and cell-mediated immunity (Franco et al., 2006). Following RVA infection, the innate immune system (mediated by macrophages, interferons, and cytokines) is rapidly triggered, which provides a potent antiviral state by suppressing the RVA replication in the host cell (Angel et al., 2012).

Diagnostic testing

RVA AGE cannot be diagnosed without laboratory tests. Diagnosis of RVA infection relies on direct viral detection from fecal specimens (Banyai et al., 2018). Several immunological and molecular techniques have been developed to detect, genotype, and characterize RVA strains in stool samples (Table 2).

Table 2 Comparison of different types of assays for rotavirus group A (RVA) detection, genotyping, and strain characterization.

Assay method	Assay name	Cost	Time	Throughput	Sensitivity	Specificity	Advantages	Disadvantages	References
Detection	Electron microscopy	High	Days	Low	Low	High	High specificity	Subjective interpretation of results	Flewett et al. (1974)
	Cell culture isolation	Low	Days	Low	Medium	Low	Low cost	Low throughput, prone to contamination	Ward et al. (1984) and Arnold et al. (2009)
	Poly acrylamide gel electrophoresis (PAGE)	Low	Days	Low	Low	High	RV detection and electropherotype determination	Low throughput, labor intensive	Herring et al. (1982) and Matsui et al. (1990)
	Enzyme immuno assay (EIA)	Low	Hours	High	Medium	High	High throughput	Variable sensitivity and specificity of different EIA kits	Dennehy et al. (1988) and Gautam et al. (2013)
	Latex agglutination	Low	Hours	High	Low	Low	Least complex	Low sensitivity and specificity	Cevenini et al. (1983)

RVA detection assays

RVA detection assays have included EM, cell culture isolation, polyacrylamide gel electrophoresis (PAGE) of viral segments, enzyme immunoassays (EIAs), latex agglutination tests, immunochromatographic tests, RT-PCR and real time or quantitative RT-PCR (qRT-PCR), but only Ag-detection EIAs and singleplex/multiplex PCR assays are used widely today. Several multipathogen diagnostic kits are commercially available to rapidly detect enteric pathogens in a high throughput format, including the Luminex Gastrointestinal Pathogen Panel (xTAG GPP) and Film Array Gastrointestinal Panel (Table 2) (Esona and Gautam, 2015).

RVA serotyping and genotyping assays

RVAs are traditionally classified based on the serologic/genetic characteristics of the aforementioned outer capsid proteins VP7 (G) and VP4 (P) that elicit neutralizing antibodies in the host. During RVA surveillance studies, both G and P serotypes/genotypes are monitored because they reassort independently from one another in vivo. RVA strains can be characterized for VP7 and VP4 by molecular-based assays, including RT-PCR and qRT-PCR, which have increased sensitivity, higher throughput, and faster turnaround time (Table 2) (Esona and Gautam, 2015).

RVA genotyping by sequencing assays

Sequence analysis is the definitive method for confirmation of RVA genotypes. Since the 1990s, the Sanger dye-termination sequencing method has been the most widely used method of automated DNA sequencing of VP7 and VP4 RVA genes. Currently, the genetic characterization of all 11 RVA genes (Esona and Gautam, 2015) is typically accomplished using next generation sequencing platforms such as the Illumina MiSeq (Illumina, San Diego, CA) (Katz et al., 2019; Sarkar et al., 2020) or the Nanopore MinIon (Oxford Nanopore Technology, United Kingdom). Whole genome level characterization enables identification of reassortant strains beyond VP7 and VP4 genotyping. (Kim et al., 2020) (Table 2).

Epidemiology

RVAs are a major cause of AGE in infants and children <5 years of age in both high- and lower-income countries; however, RVAs can cause illness in adults and has been estimated to cause >200,000 deaths globally per year across all ages (Banyai et al., 2018; Global Burden of Disease (GBD) Collaborators, 2018; Tate et al., 2016). Although infection and severe disease from RVA are prevalent worldwide, >90% of annual RVA deaths globally occur in developing countries, where ready access to rehydration therapy is less available (Banyai et al., 2018; Tate et al., 2016). Infections in the first 3 months of life are generally milder, probably because of protection from maternal antibodies. Children aged 4–23 months are at greatest risk for severe RVA disease, with frequent infections due to lack of immunity and more frequent exposure (Velazquez et al., 1996). Immunity progressively increases with each subsequent infection, and thus symptoms are milder upon reinfection (Greenberg and Estes, 2009).

RVA infection can remain asymptomatic or lead to AGE with mild to severe diarrhea, vomiting, and fever, resulting in dehydration, electrolyte imbalance, abdominal cramps, and death in some cases (Bernstein, 2009). RVA are shed in high concentrations in the stools of infected children and are transmitted primarily by the fecal-oral route, both through close person-to-person contact and through fomites (Butz et al., 1993). Infected children start shedding RVA in their stools before onset of symptoms and may excrete more than 10^{10} – 10^{11} RVA particles per gram of feces. RVA is highly contagious and requires <100 virus particles to cause infection in a susceptible person (American Academy of Pediatrics, 2003). RVA symptoms subside within days in immunocompetent children but can last for several months in immunocompromised children (Saulsbury et al., 1980). RVA infections in adults are generally asymptomatic or cause milder symptoms, but symptomatic infections, including moderate to severe illness, have been observed in older adults (Burke et al., 2018, 2021; Cardemil et al., 2012; Pacilli et al., 2015).

RVA AGE shows prominent winter seasonality in many higher-resource countries, with infection prevalence substantially decreasing during summer months. In many developing countries, however, RVA disease is less seasonal and may occur year-round; seasonal peaks can occur during the dry season in tropical climates (Chao et al., 2019; Levy et al., 2009; Patel et al., 2013).

Vaccines and other methods of control

Prior to RVA vaccine introduction, RVA infections caused about 40% of AGE hospitalizations in children <5 years of age worldwide. In 2009, The World Health Organization (WHO) recommended inclusion of RVA vaccines in national immunization programs globally, as an optimal strategy to decrease the burden associated with severe and fatal RVA diarrhea worldwide (World Health Organization, 2009; Global Burden of Disease (GBD) Collaborators, 2018; Patel et al., 2011). This led to substantial reductions in AGE-related hospitalizations, emergency department visits, and mortality in countries that introduced the vaccine (Ai et al., 2020; Aliabadi et al., 2019; Burnett et al., 2017; Cortese et al., 2009). Among children <5 years of age, the median percentage reduction in AGE hospitalizations was 38% overall and 41%, 30%, and 46% in countries with low, medium, and high child mortality, respectively. Hospitalizations and emergency department visits due to RVA AGE were reduced by a median of 67% overall and 71%, 59%, and 60% in countries with low, medium, and high child mortality, respectively (Burnett et al., 2017).

Four live attenuated, oral RVA vaccines—RotaTeq[®] (Merck and Co., West Point, PA), Rotarix[®] (GlaxoSmithKline Biologicals, Rixensart, Belgium), ROTAVAC[®] (Bharat Biotech, Hyderabad, India) and Rotasiil[®] (Serum Institute of India, Pune, India)—have been WHO prequalified and introduced into the national vaccination program in more than 100 countries (Fig. 4) (International Vaccine Access Center (IVAC), 2021; Banyai et al., 2018).

Fig. 4 Countries that have introduced Rotavirus group A (RVA) vaccine into immunization schedules (regional or national), 2021. Data from International Vaccine Access Center (IVAC) (2021) Johns Hopkins Bloomberg School of Public Health. Available online: www.view-hub.org.

RotaTeq®: In 2006, RotaTeq® was licensed by the FDA and recommended by the Advisory Committee on Immunization Practices (ACIP) for routine vaccination of U.S. infants; in 2008, the vaccine was prequalified by WHO. RotaTeq® is a pentavalent (G1, G2, G3, G4, P[8]) human-bovine reassortant vaccine administered orally to infants as 3 doses, 4 weeks apart, beginning as early as 6 weeks of age (Cortese et al., 2009; Dennehy, 2008). In clinical trials and observational studies in high-income settings such as the United States and Finland, RotaTeq® was highly efficacious, reducing incidence of medical office visits by 86%, emergency department (ED) visits by 94%, and RVA-associated AGE hospitalizations by 96% (Vesikari et al., 2006). RotaTeq® vaccine effectiveness is lower (45%), however, in low-income countries with high child mortality (Burnett et al., 2018).

Rotarix®: In 2008, ACIP recommended Rotarix® vaccine for routine vaccination of U.S. infants; in 2009, the vaccine was prequalified by WHO. Rotarix® contains a live, attenuated monovalent G1P[8] human RVA strain and is recommended for oral administration to infants in 2 doses, at least 4 weeks apart, beginning at 6 weeks of age (Cortese et al., 2009). In a randomized, double-blind, placebo-controlled study conducted in 6 European countries, Rotarix® was highly immunogenic and efficacious. Its efficacy through 2 RVA seasons against severe AGE was 90% and in reducing hospitalizations was 96% (Vesikari et al., 2004, 2007). Rotarix® vaccine effectiveness is lower (57–75%) in medium and low-income countries with high child mortality (Burnett et al., 2018).

ROTAVAC®: In 2018, ROTAVAC® vaccine received WHO prequalification. This live attenuated vaccine is derived from a naturally occurring human reassortant strain 116E (G9P[11]) isolated from an Indian child. The ROTAVAC® vaccine is administered orally in 3-dose series 4 weeks apart, beginning at 6 weeks of age up to 8 months of age. In a clinical trial in India, the efficacy of ROTAVAC® for severe non-vaccine RVA AGE was 56.4% in the first year of life and 49% in the second year (Bhandari et al., 2014).

Rotasiil®: In 2018, Rotasiil® vaccine received WHO prequalification. Rotasiil® is a live attenuated bovine-human reassortant RVA vaccine [BRV-PV] containing RVA serotypes G1, G2, G3, G4, and G9. It is administered as a 3-dose regimen at 6, 10, and 14 weeks of age. Rotasiil® is the world's first thermostable RVA vaccine, able to be transported at ambient temperature and stored at <25 °C. In a clinical trial of Indian infants, the vaccine efficacy of Rotasiil® against the very severe RVA cases (Vesikari score ≥ 16) was 60.5% at the time of the primary analysis and 54.7% for the complete follow-up period; results from a trial in Niger were similar (Isanaka et al., 2017; Kulkarni et al., 2017).

Nationally licensed RVA vaccines

Two additional live, attenuated orally administered RVA vaccines—Lanzhou Lamb (Lanzhou Institute of Biological Products) and Rotavin-M1 (POLYVAC Center for Research and Production of Vaccines Vietnam)—have obtained national licensure (Table 3).

Lanzhou Lamb (LLR): The Lanzhou Lamb vaccine is a live, attenuated oral vaccine licensed in China in 2000. It contains a G10P[12] lamb RVA strain isolated in 1985. This vaccine is administered to children aged 2–36 months, one dose between 6 and 12 months of age followed by yearly boosters. LLR vaccine effectiveness estimates have ranged from 35% to 53% among children <3 years of age (Fu et al., 2012; Zhen et al., 2015).

Rotavin-M1™: Rotavin-M1™ vaccine is a live, attenuated oral vaccine that was licensed for use in Vietnam in 2012. This vaccine contains a G1P[8] human RVA strain (KH0118-2003) isolated from a child in Vietnam (Dang et al., 2012). Rotavin-M1™ is administered orally in a 2-dose schedule, with the first dose at age 6 weeks or later and the second dose 60 days after the first. Rotavin-M1™ vaccine is safe and immunogenic, with an RVA IgA seroconversion rate of 73% in a trial of Vietnamese infants (Skansberg et al., 2021).

Table 3 Key characteristics of currently WHO prequalified and nationally licensed rotavirus group A (RVA) vaccines.

Name	Manufacturer	Composition	Doses	Formulation/Storage and Shelf life	Licensure	Study sites for phase III Trials	Efficacy	Safety
RotaTeq® (RV5)	Merckand Co.	Live attenuated bovine-human reassortant strains, G1, G2, G3, G4, P1[8]	3	Liquid/2–8 °C for 24 months	WHO pre-qualified in 2008	Bangladesh, Belgium, Costa Rica, Finland, Germany, Ghana, Guatemala, Italy, Kenya, Mali, Mexico, United States, Sweden, Taiwan, Vietnam	51–64% in developing countries and 94–100% in developed countries	WHO concluded that the benefits of rotavirus vaccination exceeded the risk of intussusception
Rotarix® (RV1)	GSK Biologics	Live human-attenuated rotavirus strain, G1P [8]	2	Liquid/2–8 °C for 36 months	WHO pre-qualified in 2009	Argentina, Brazil, Chile, Colombia, the Dominican Republic, Finland, Honduras, Malawi Mexico, Nicaragua, Panama, Peru, Venezuela, South Africa	49–72% in developing countries and 72–97% in developed countries	WHO concluded that the benefits of rotavirus vaccination exceeded the risk of intussusception
ROTAVAC® (RV1)	Bharat Biotech, India and PATH, United States	Live attenuated neonatal rotavirus strain, G9P[11] (aka 116E)	3	Liquid/2–8 °C for 6 months Frozen/–20 °C for 5 years	WHO pre-qualified in 2018	India	56% in India	Intussusception risk in vaccinated group was not higher than in placebo group. No increased risk seen in several observational studies
ROTASIL® (RV5)	Serum Institute of India, India and PATH, United States	Bovine-human reassortant rotavirus vaccine, G1, G2, G3, G4, G9	3	Lyophilized/<40 °C for 18 months Lyophilized/<25 °C for 30 months	WHO pre-qualified in 2018	India and Niger	66% in Niger and 39% in India	Intussusception risk in vaccinated group was not higher than in placebo group
Lanzhou Lamb Rotavirus (LLR) (RV1)	Lanzhou Institute of Biological Products, China	Live attenuated lamb rotavirus strain, G10P [12]	5	Liquid/–20 °C for 30 months	In China	China	Not applicable	Not known
Rotavin-M1™ (RV1)	POLYVAC, Vietnam	Live attenuated human rotavirus strain, G1P [8]	2	Liquid/2–8 °C for 2 months Frozen/–20 °C for 24 months	In Vietnam	Vietnam	Not applicable	Not known

Burke RM, Tate JE, Kirkwood CD, Steele AD and Parashar UD (2019) Current and new rotavirus vaccines. *Current Opinion in Infectious Diseases* 32(5): 435–444.

RVA vaccines under development

Several RVA vaccine candidates are under clinical development utilizing different strains, formulations, and routes of administration to overcome challenges associated with live, attenuated oral vaccines (Burke et al., 2019). The candidate vaccine RV3-BB (PT BioFarma, Bandung, Indonesia) is an oral vaccine based on a naturally attenuated neonatal strain of G3P[6] RVA and has the ability to replicate in the newborn gut even in the presence of maternal antibodies (Bines et al., 2018).

Non-replicating parenterally delivered RVA vaccines are considered an alternative to the current live oral vaccines. The advantages of these vaccines are improved vaccine safety with respect to intussusception, improved efficacy due to lack of competition from maternal antibodies, and lower manufacturing costs (Kirkwood et al., 2019). Some non-replicating RVA vaccine candidates are inactivated RVA vaccine (Resch et al., 2018; Wang et al., 2010), expressed proteins (based on VP6 inner capsid) (Lappalainen et al., 2015), virus-like particles (Bertolotti-Ciarlet et al., 2003), and VP8* expressed proteins (Groome et al., 2017).

Norovirus

History

Norwalk virus, the prototype strain of genus *Norovirus* within the family *Caliciviridae*, was identified in 1972 by immune EM (IEM) of fecal specimens obtained from human volunteers who had ingested stool filtrates from a gastroenteritis outbreak at a school in Norwalk, Ohio that had occurred in 1968 (Kapikian, 2000; Kapikian et al., 1972). Several other norovirus reference strains, such as Hawaii virus and Snow mountain virus, were subsequently discovered in 1977 and 1982, respectively (Dolin et al., 1982; Thornhill et al., 1977). Noroviruses, named after the prototype Norwalk virus, are now recognized as a major cause of epidemic and sporadic acute gastroenteritis among humans of all ages.

Morphology, structure, and nomenclature

Noroviruses consist of a single-stranded RNA in a nonenveloped icosahedral capsid. They are small round viruses 27–35 nm in diameter (Fig. 1). Two major domains can be found in the capsid: the shell (S) and the protruding arms (P). The S domain represents the inner part of the capsid that surrounds the genome, while the P domain forms the archlike capsomeres that protrude from the virion. Norovirus virions contain 180 copies, or 90 dimers, of capsid protein, forming a shell from which 90 archlike dimers protrude. Norovirus has $T = 3$ icosahedral symmetry. Unlike other caliciviruses, norovirus virions do not display a typical cup-like morphology (Glass et al., 2009; Robilotti et al., 2015).

The norovirus genome is composed of a linear, positive-sense RNA that is approximately 7.6 kb in length and covalently linked to the viral protein genome (VPg) at the 5' end and polyadenylated at the 3' end (Jiang et al., 1993; Thorne and Goodfellow, 2014). There are three open reading frames (ORFs), designated ORF1, ORF2, and ORF3, encoding eight viral proteins (Fig. 5). ORF1 encodes a polyprotein that is proteolytically processed into the 6 nonstructural proteins, including the norovirus protease and RNA-dependent RNA polymerase (Thorne and Goodfellow, 2014). ORF2 encodes a viral capsid protein (VP1) with a significant role in virus replication, and ORF3 codes for a small basic protein (VP2) which interacts with genomic RNA during virion formation (Robilotti et al., 2015; Thorne and Goodfellow, 2014).

Norovirus is one of the eleven genera in the family *Caliciviridae* (Vinje et al., 2019). Based upon phylogenetic analysis and $2 \times$ standard deviation of VP1, they are currently classified into 10 genogroups (GI–GX), and the genogroups can be further subdivided into 48 genetic clusters or genotypes (Chhabra et al., 2019). Viruses belonging to GI and GII are most frequently associated with human infections. Of the 35 genotypes that have been detected in humans, GII.4 viruses are the predominant circulating genotype causing outbreaks worldwide (Bull et al., 2006; Glass et al., 2009; Robilotti et al., 2015). The rapid evolution of GII.4 variants has

Fig. 5 The human norovirus genome. The genome is comprised of a linear, positive-sense RNA, 7.3–8.3 kb in length, covalently linked to the viral protein genome (VPg) at the 5' end and polyadenylated at the 3' end. There are three open reading frames (ORFs), designated ORF-1, ORF-2, and ORF-3, encoding 8 viral proteins. ORF-1 encodes the 6 nonstructural (NS) proteins that are proteolytically processed by the virally encoded cysteine proteinase (Pro). ORF-2 and ORF-3 encode the structural components of the virion, major capsid protein 1 (VP1) and minor capsid protein 2 (VP2), respectively. VP1-Major capsid protein. VP2-Minor capsid protein. p48 (NS1/NS2)-N-term (amino terminal protein). NTPase (NS3)-Nucleoside triphosphatase. P22 (NS4)-3A-like protein. VPg (NS5)-Genome-linked viral protein. Pro (NS6)-Proteinase. Pol (NS7)-RNA-dependent RNA polymerase. From Amir Yunus M (2021) Molecular Mechanisms for Norovirus Genome Replication, in *Norovirus*. IntechOpen, doi:10.5772/intechopen.96032.

led to the emergence of novel strains associated with global epidemics, as new norovirus strains are capable of infecting newly susceptible populations lacking protective immunity (van Beek et al., 2018).

Replication and pathogenesis

As in all other positive-strand RNA viruses, norovirus replication begins with the attachment of the VP1 protein of the viral particles through a specific receptor on the membrane of the host cell. In the case of norovirus, the specific cellular receptor is currently unknown. However, several binding ligands have been described, including HBGA and bile acids (Campillay-Veliz et al., 2020; Lin et al., 2014, 2020; Marionneau et al., 2002; Tan et al., 2003), which have been linked to susceptibility to norovirus in a genotypic-specific manner (Huang et al., 2003; Lindesmith et al., 2003). Individuals with two non-functional copies of *FUT2* are termed “non-secretors,” as they do not produce the H-type 1 antigen in saliva or epithelial cells. Non-secretors have been found to be resistant to norovirus infections, particularly those caused by GII viruses (Reyes et al., 2021; Thorven et al., 2005).

Following viral entry, virions are disassembled and viral RNA is released into the cytoplasm. The exact mechanism by which these two processes take place is not yet known for noroviruses. Once the viral genome is released, the VPg protein, which is covalently linked at the 5′ end of the viral genome, starts the translation process (Daughenbaugh et al., 2003) and generates three protein precursors—p48/NTPase, p22/VPg, and Pro/Pol—that are needed to carry out the replication process (Campillay-Veliz et al., 2020). A viral polyprotein is produced from the translation of the viral genome, and VP1 and VP2 proteins are generated from the sub-genomes (Cao et al., 2007). The structural proteins then assemble in complete virions which are released through a mechanism that remains to be elucidated (Fig. 6) (Campillay-Veliz et al., 2020; Hutson et al., 2002).

Noroviruses infect predominantly by the oral route, and most infections result in mild and self-limiting illness. Symptom onset, in particular vomiting, is frequently abrupt, and usually occurs within 12–48 h after exposure (Robilotti et al., 2015). Human volunteer studies have shown that noroviruses have a low infectious dose (median infectious dose <20 virus particles) and that infected persons excrete viruses in large amounts (10^8 to 10^{10} copies of RNA per gram of feces). Norovirus shedding can continue for >2 weeks after the symptomatic phase of the disease, as well as in cases of asymptomatic infection (Okhuysen et al., 1995; Parashar et al., 1998). There is little evidence that noroviruses cause chronic infections; however, a study performed in immunocompromised children and adolescents reported norovirus shedding for at least 8 months (Levett et al., 1996).

The virus replicates in intestinal epithelial cells (Karandikar et al., 2016), observed in adult volunteers infected with Norwalk virus (Green, 2013). The mechanisms responsible for diarrhea are not known, but the lesions caused by blunting of the intestinal villi may cause disruption of ion transport (Green, 2013). The development and refinement of human intestinal enteroids for cultivating human noroviruses has led to substantial advances in the understanding of viral replication and host-pathogen interactions (Chan et al., 2021; Costantini et al., 2018; Estes et al., 2019; Ettayebi et al., 2016, 2021; Karandikar et al., 2016; Karst and Tibbetts, 2016). These enteroids are now being used to study the cellular processes and signaling pathways involved in restricting replication of human noroviruses.

Clinical manifestation

Individuals infected with norovirus typically present with symptoms consistent with acute gastroenteritis, which include one or more of the following: nausea, vomiting, abdominal pain and cramps, diarrhea, myalgias, headache, and chills. Norovirus presents as a vomiting-only disease more frequently than other enteric viruses, particularly among young children (Burke et al., 2021; Vanderkooi et al., 2019). Symptoms may develop with or without early signs and typically persist for 1–3 days (Atmar et al., 2018; Banyai et al., 2018; Sell and Dolan, 2018). Treatment is aimed toward prevention of dehydration and includes either oral rehydration or intravenous administration of fluids. Moderately to severely dehydrated infected individuals may show signs such as tachycardia, orthostatic hypotension, decreased skin turgor, and dry mucous membranes. In severe cases, infection can lead to death due to dehydration. Rarely, infected individuals may present with significant neurologic symptoms such as a seizure or encephalopathy (Green, 2013; Randazzo et al., 2018; Robilotti et al., 2015).

Diagnostic testing

Diagnostic testing available for norovirus includes real-time reverse transcriptase-polymerase chain reaction (RT-qPCR, multi-gastrointestinal-pathogen diagnostic platforms (such as Luminex xTAG GPP, Biofire FilmArray GI and Verigene Enteric Pathogens Test), and commercial EIAs (Chhabra et al., 2017; Green, 2013; Vinje, 2015). RT-qPCR is presently regarded as the gold standard for norovirus detection, being both sensitive and specific as well as able to provide results within hours (Morillo and Timenetsky Mdo, 2011; Vinje, 2015). However, this method requires skilled technicians and specialized equipment and facilities. Although less sensitive than RT-qPCR, ELISA and lateral flow assays (such as IDEIA Norovirus EIA, SRSV (II)-AD, and RIDASCREEN) allow for rapid detection of viral proteins in fecal specimens (Green, 2013), and their ease of use, cost effectiveness, ability to detect a range of genotypes, and ability to provide results within hours make them useful for confirming norovirus as the etiology in outbreak settings. Norovirus can also be genotyped by sequence analysis of an RT-PCR product encompassing the 3′-end of the polymerase gene (region B) and 5′-end of the capsid gene (region C) in a single reaction for either genogroup I or genogroup II noroviruses (Chhabra et al., 2021). Sequences can then be typed using online typing tools such as <https://www.rivm.nl/mpf/norovirus/typingtool> or <https://norovirus.ng.philab.cdc.gov/> (Tatusov et al., 2021). Both typing tools use the exact same reference sequences (Chhabra et al., 2019).

Fig. 6 The composition and replication cycle of human noroviruses. The viral capsid protein attaches to the cell surface through interactions between VP1 and host histo-blood group antigens (HBGAs) (step 1), and is subsequently internalized, uncoated and disassembled (steps 2, 3). The (+)RNA is then transcribed and translated in the cytoplasm of the host cell. Translation is mediated by host translation factors that are recruited by the non-structural virus protein VPg, which covalently binds to the 5' end of the genome (step 4). The polyprotein that is encoded by ORF1 is post-translationally cleaved (step 5) by the virus-encoded protease, Pro (also known as NS6 or 3C-like), into individual proteins: p48 (also known as NS1/2 or N-term), NTPase (also known as NS3 or 2C-like), p22 (also known as NS4 or 3A-like), VPg, Pro and RNA-dependent RNA polymerase (RdRp). During genome replication, (+)RNA is transcribed into negative-sense RNAs (–)RNAs, which are used as templates for the synthesis of new genomic and subgenomic (+)RNAs, respectively (step 6). Subgenomic (+)RNAs contain only ORF2 and ORF3 and are used for the production of VP1 and VP2. During encapsidation (step 7), genomic- and possibly subgenomic- (+)RNAs are packaged into new virions, which are subsequently released from the infected host cell (step 8), although the mechanism by which release occurs remains largely unknown. Used with permission from De Graaf M, Van Beek J, and Koopmans MPG (2016) Human norovirus transmission and evolution in a changing world. *Nature Reviews Microbiology* 14(7): 421–433.

Epidemiology, transmission, prevention, and control

Noroviruses are a leading cause of AGE worldwide, with estimated annual episodes ranging as high as 684 million and estimated annual deaths as high as 200,000 (Kirk et al., 2015). Norovirus burden is particularly high among older adults and young children (Burke and Hall, 2019). Noroviruses are one of the leading causes of severe gastroenteritis in children <5 years of age globally; as wider use of RVA vaccines has decreased RVA burden, prevalence of norovirus has increased among young children (Hassan et al., 2019; McAtee et al., 2016; Payne et al., 2013). Noroviruses are distributed globally with GII.4 viruses being more common than GI viruses (Vega et al., 2014). Norovirus cause both outbreaks and sporadic acute gastroenteritis. Outbreaks occur regularly in crowded or congregate living settings such as childcare centers, hospitals, nursing homes, restaurants, and cruise ships (Wikswa et al., 2021). Norovirus is extremely contagious. Though aerosol spread of norovirus is possible, transmission occurs mostly via fecal-oral and vomit-oral pathways by four general routes: direct person-to-person, foodborne, waterborne, or through environmental fomites. Since humans are the only known reservoir of human norovirus, all transmission is ultimately person-to-person (Gotz et al., 2001; Lopman et al., 2016). Though several norovirus vaccine candidates are in development, there are presently no licensed vaccines or antiviral therapies for norovirus gastroenteritis (Cates et al., 2020). Prevention and control strategies for norovirus are limited to standard infection control guidelines, such as hand hygiene, cleaning and disinfection of diarrhea or vomitus, and work exclusions where appropriate (Lopman et al., 2016).

Enteric adenoviruses

History

Adenoviruses were first isolated and characterized from human lymph nodes in 1953 (Rowe et al., 1953). The first adenovirus identified was isolated from adenoidal tissue of children and named “adeno” after the Greek word for gland (Rowe et al., 1953). Adenoviruses are ubiquitous, have been isolated from nearly every class of vertebrates, and are species-specific (Berk, 2013; Strauss and Strauss, 2002). Today, adenoviruses cause various human diseases, including acute gastroenteritis, respiratory tract infections, conjunctivitis, and in rare cases acute hemorrhagic cystitis, meningitis, and pneumonia (Berk, 2013; Ghebremedhin, 2014). This section will focus on adenoviruses that cause acute gastroenteritis.

Morphology, structure, and nomenclature

Adenoviruses are non-enveloped icosahedral particles with virions of an estimated 70–100 nm in diameter. The virions exhibit a characteristic icosahedral capsid layer of 252 capsomers of which 240 have a six-fold symmetry (hexons) and form facets, and 12 have a five-fold symmetry (pentons) and form vertices. Fiber-like projections protruding from the pentameric penton base proteins at the vertices of the icosahedron are responsible for host receptor binding. Additional proteins (pIIIa, pVI, pVIII, and pIX) are located on the capsid. The capsid surrounds a DNA-containing core that consists of a single copy of DNA with proteins such as the terminal protein (TP), polypeptide (pV), pVII, and pX (Fig. 7) (Berk, 2013; Davison et al., 2003; Ginsberg et al., 1966; Goncalves and de Vries, 2006; Russell, 2000; Seiradake and Cusack, 2005).

The adenovirus genome consists of double-stranded (ds) DNA ranging about 26–45 kbp in length. Structurally, the genome is linear and non-segmented and encodes for more than 30 structural and non-structural proteins. The genome has a terminal 55 kDa protein that is linked to the dsDNA 5'-ends, where it is used as a primer during replication (Berk, 2013; Chaberny et al., 2003;

Fig. 7 Structure and genome of adenovirus. (A) Depiction of adenovirus structure and different proteins. (B) Adenovirus genome organization showing various early (E) and late (L) transcripts and proteins encoded by each transcript. Red indicates early and black indicates late. From Singh S, Kumar R, and Agrawal B (2019) *Adenoviral Vector-Based Vaccines and Gene Therapies: Current Status and Future Prospects*, IntechOpen.

Friefeld et al., 1984). In addition, the genome encodes for several transcription units: early units (E1A, E1B, E2, E3, and E4), intermediate units, and a major late transcription unit (Fig. 2) (Berk, 2013; Ruuskanen et al., 2002).

Classification and nomenclature

Adenoviruses are classified into five genera (*Mastadenovirus*, *Aviadenovirus*, *Atadenovirus*, *Siadenovirus*, and *Ichtadenovirus*) based on the host from which they were first isolated (Berk, 2013). Of those, only members of *Mastadenovirus* cause human infections (International Committee on Taxonomy of Viruses, 2018. <https://talk.ictvonline.org/taxonomy/>). Currently, human adenovirus (HAdV) is classified into nine subgroups (A to I): within each subgroup, 90 genotypes have been identified (International Committee on Taxonomy of Viruses, 2018. <https://talk.ictvonline.org/taxonomy/>; Human Adenovirus Working Group, 2018. Available from: <http://hadvwg.gmu.edu/>; Ghebremedhin, 2014). Although other adenovirus types have been associated with gastrointestinal infections, only viruses belonging to subgroup F (genotypes 40 and 41) have been associated with acute gastroenteritis and are responsible for an estimated 5–20% of acute gastroenteritis in young children (Banerjee et al., 2017; Kim et al., 2017; Qiu et al., 2018; Uhnoo et al., 1984).

Replication and pathogenesis

Adenoviruses replicate in the nucleus (Fig. 8). First, the virion attaches to the host cell by binding its glycoprotein fiber structure to an adenovirus-specific receptor followed by interaction of the penton base with cellular integrin, which promotes receptor-mediated internalization (Leen and Rooney, 2005). Next, the virus is internalized into the clathrin-coated endosome, which due to its high pH helps uncoat the virus and transport viral DNA through microtubules into the nucleus. At this point, early transcripts undergo translation to produce about 20 different early proteins that induce the host cell to enter into the S-phase of the cell cycle and to create conditions favorable for viral replication (Shenk, 2001). DNA replication takes place in the nucleus as the 5' end of the viral DNA strand acts as a primer for initiation of viral DNA synthesis (Goncalves and de Vries, 2006; Shenk, 2001). During late transcription/translation and viral morphogenesis and release, a large single primary transcript is synthesized from viral DNA that is spliced into 18 fragments; each fragment acts as mRNA and is transported to the cytoplasm, where translation occurs and viral structural proteins are synthesized. Viral DNA then gets packaged into preformed capsid-forming mature virus particles that are stable, infectious, and resistant to nuclease enzyme of a host cell. Finally, the mature virus is released from the host cell by budding (Berk, 2013; Lenaerts et al., 2008).

Adenoviruses can infect and replicate in epithelial cells of the gastrointestinal tract and various viral factors contribute to pathogenesis. One unique feature of adenovirus is that its penton protein has a toxic effect on cells leading to atrophy of the villi and

Fig. 8 A schematic illustration of the adenovirus infection and replication cycle. Used with permission from Waye MMY and Sing CW (2010) Anti-viral drugs for human adenoviruses. *Pharmaceuticals* 3(10): 3343–3354.

compensatory hyperplasia in the crypts with subsequent malabsorption and loss of fluids (Berk, 2013; Fox et al., 1977; Wadell et al., 1999). Adenovirus infection results in an immune response that probably renders long-lasting protection against re-infection with the same virus type (Berk, 2013).

Clinical manifestation

The symptoms caused by adenovirus types 40 and 41 are typically mild and self-limiting, and infections occur throughout the year, mostly in young children. Patients normally present clinical symptoms such as acute watery diarrhea and vomiting (Hierholzer, 1992; Scott et al., 2016). The incubation period of adenoviruses is 8–10 days, and diarrhea can last 3–11 days. Illness can be severe in immunodeficient patients and, although rarely, infection can lead to chronic diarrhea (Berk, 2013; Bresee et al., 1999).

Diagnostic testing

Laboratory diagnosis of adenovirus infection requires (Martin and Kudesia, 1990) isolation of virus in cell culture (Berk, 2013), demonstration of antigen-infected cells by immunofluorescence (IF) (Tsutsumi et al., 1999), detection of virus antigen by EIA (Fodha et al., 2006), demonstration of viral nucleic acid by molecular-based assays such as PCR (Reither et al., 2007), or demonstration of IgM antibody or a four-fold rise in antibody titer in blood specimens (Berk, 2013). Adenoviruses can also be detected using multipathogen assays such as Luminex Gastrointestinal Pathogen Panel (Navidad et al., 2013), TaqMan Array Card (Liu et al., 2013), and Film Array Gastrointestinal Panel (Reddington et al., 2014).

Epidemiology, transmission, prevention, and control

Adenoviruses are widespread in nature and infect mammals and birds. They cause a variety of symptoms and are an important cause of acute gastroenteritis in children <5 years of age, responsible for an estimated 15% of all childhood diarrhea (Clark and McKendrick, 2004; Hassan et al., 2019; Koopmans, 2005; Lee et al., 2020). The transmission of enteric adenoviruses occurs via the fecal-oral route, and they can be transmitted from person to person (direct contact) or via environmental routes (Bresee et al., 1999). Adenoviruses have been linked with outbreaks in communities such as schools, day-care centers and military camps, and the virus is able to contaminate environmental sources including food and water (Filho et al., 2007; Fong and Lipp, 2005; Huh et al., 2009; Lazic et al., 2015; Mattison et al., 2021).

There are currently no publicly available vaccines or antivirals against adenovirus infections. Whole-virus vaccines are not used because of the potential risk of oncogenesis. Other vaccines, including recombinant vaccines, are under development (Doerfler, 1996).

Astrovirus

History

In 1975, Appleton and Higgins used EM to detect viral particles of 28–30 nm in size in stools of children suffering from vomiting and diarrhea (Appleton and Higgins, 1975). Later that year, Madeley and his colleague reported occurrence of the same viral particles in feces of infants hospitalized with gastroenteritis and in outbreaks of gastroenteritis in newborn nurseries (Madeley and Cosgrove, 1975). They used the term astrovirus to describe these viruses.

Morphology, structure, and nomenclature

The name astrovirus is derived from the Greek word “astron,” which means star. Visualized by EM, astrovirus virions have a well-defined five- or six-pointed, star-like appearance with a white center and triangular surface hollows (Mendez and Arias, 2013). They are small icosahedral nonenveloped particles with a smooth margin; the distinctive star shape is visible on the surface of approximately 10% of astrovirus virions (Mendez and Arias, 2013). The astrovirus genome is a positive-sense single-stranded polyadenylated RNA molecule of 6.8–7.9 kb in length. It contains three ORFs, named from the 5′ end to the 3′ end, ORF1a, ORF1b, and ORF2. The genome consists of the 5′ and 3′ untranslated regions of 11–85 bases and 80–85 bases, respectively, and a poly-A tail at the 3′ end. ORF1a and ORF1b encode for the nonstructural proteins involved in RNA transcription and replication, while ORF2 encodes for the capsid precursor proteins, which are expressed from a sub-genomic RNA (Fig. 9) (Bosch et al., 2014; Firth and Atkins, 2010; Mendez and Arias, 2013; Monroe et al., 1993; Walter and Mitchell, 2003; Wilhelmi et al., 2003; Willcocks and Carter, 1993).

Classification and nomenclature

Astroviruses have been found in the feces of a wide variety of mammalian species (Bosch et al., 2014; Castro et al., 2013; Hoshino et al., 1981; Martella et al., 2011; Mendez and Arias, 2013), as well as avian species (Chu et al., 2012; Koci et al., 2000; Mendez and Arias, 2013). The family *Astroviridae* is divided into two genera, based on the hosts of origin: *Mamastrovirus* (MAstV) and *Avastrovirus*

Fig. 9 Genome organization human astrovirus. Genomic and subgenomic RNA organization, with open reading frames (ORFs) ORF1a, ORF1b, ORF2, and putative ORFX represented as boxes. Adapted from Bosch A, Pinto RM and Guix S (2014) Human astroviruses. *Clinical Microbiology Reviews* 27(4): 1048–74.

(AAstV), infecting mammalian (human, bovine, feline, mink, ovine, and porcine) and avian species (chicken, duck, and turkey), respectively. Within the genus MAstV there are two genogroups, GI (consisting of 10 genotype species) and GII (nine genotype species); both encompass viruses of human and animal origin (Zhu et al., 2009). Human astroviruses (HAstVs) are classified into eight distinct genotypes based on the nucleotide sequence of ORF2 (Noel et al., 1995) which correlate well with astrovirus serotypes, as defined by clear differences in neutralization. Genotypes 1 and 2 are most frequently detected worldwide (Mendez and Arias, 2013).

In the late 2000s, two divergent HAstV genotypes were discovered which are referred to as a group of non-classical astroviruses. They include the HAstV-MLB (Melbourne) clade containing at least three strains (MLB1, MLB2, MLB3) and the HAstV-VA/HMO (Virginia/Human-Mink-Ovine-like) clade containing at least five strains (VA1, VA2, VA3, VA4, VA5). (Mendez and Arias, 2013). The prevalence of these non-classical viruses varies greatly according to geographic location, and their association with clinical disease remains unclear.

Replication and pathogenesis

Viral replication is cytoplasmic, and entry into the host cell is achieved by attachment to host receptors that mediate endocytosis. Several investigators have suggested that astrovirus RNA replication is associated with membranes derived from the endoplasmic reticulum at the perinuclear region, and ultrastructural analysis has revealed the presence of viral aggregates close to the nuclear periphery surrounded by a high number of double-membrane vacuoles. Although the exact composition of these replication complexes is not known, it is likely that all nonstructural proteins are required and that the temporary regulation of protein processing of the replicase complex may play a role in the regulation of the minus- and plus-strand RNA synthesis processes. Of interest, variability within the protein encoded at the C-terminal region of ORF1a has been shown to affect the RNA replication pattern, and a functional effect of phosphorylation of the protein has been suggested. Although some nonstructural proteins have been detected by IF within the nucleus of infected cells (Fig. 10) (Bosch et al., 2014; Mendez and Arias, 2013; Speroni et al., 2009; Willcocks et al., 1999), involvement of the nuclear phase in the replication cycle of astrovirus is not fully understood.

Although a few spike crystal structures of the astrovirus spike domain have been studied and defined, little is known about their pathogenesis and how the capsid structures relate to the mechanism of pathogenesis (Dong et al., 2011). Common mechanisms involved in astrovirus pathogenesis include destruction, distention, and thinning of the intestines as well as fluid accumulation due to inhibition of usual absorption mechanisms, loss of secretory functions, and reduction in epithelial permeability in the intestines (Bosch et al., 2014; Mendez and Arias, 2013).

Clinical manifestation

The main clinical symptom of HAstV infection is self-limiting acute gastroenteritis, which on rare occasions has been shown to cause systemic infection in immunocompromised individuals (Wunderli et al., 2011). Symptoms typically last 2–3 days. Some non-classical astroviruses have also been associated with central nervous system infections mostly in immunocompromised patients (Espul et al., 2004; Sato et al., 2016). Viruses can be excreted in feces for up to 14 days, although shedding can be prolonged in immunodeficient patients. Asymptomatic excretion of astroviruses can occur in up to 20% of young children (Caballero et al., 2003; Clark and McKendrick, 2004; Espul et al., 2004).

Diagnostic testing

Laboratory assays to detect astroviruses include EIAs and RT-qPCR (Beuret, 2004; Glass et al., 1996; Kurtz and Lee, 1987; Mendez and Arias, 2013; Risco et al., 1995). The classical astroviruses (types 1–8) can also be detected using multipathogens assays such as TaqMan Array Card (Liu et al., 2013) and Film Array Gastrointestinal Panel (Reddington et al., 2014).

Fig. 10 Replication cycle of human astroviruses. (A) Synthesis of the 90 kDa human astroviruses (HAsV) capsid protein (VP90) from viral subgenomic RNA (sgRNA); (B) assembly of VP90 proteins (180 copies) with viral genomic RNA into HAsV particles; (C) caspase-mediated cleavage of VP90 C-termini to form VP70 and subsequent release of immature HAsV particles; (D) extracellular protease cleavage of immature HAsV particles to form mature, infectious HAsV particles. In cell culture, trypsin is used to produce mature, infectious HAsV particles; (E) extracellular HAsV particles induce host antibody production and inhibit host complement activation; (F) attachment and clathrin-dependent endocytosis of HAsV particles; (G) Uncoating of the virus genome in the late endosome. Extracellular signal-regulated kinase (ERK1/2) and phosphoinositide 3-kinase (PI3K) are activated during HAsV binding or entry into the cell. From Arias C and Dubois R (2017) The astrovirus capsid: A review. *Viruses* 9(1): 15.

Epidemiology, transmission, prevention, and control

Astroviruses are distributed worldwide, typically infect the young of mammalian and avian species, and account for an estimated 10% of all sporadic human diarrhea cases (Mendez and Arias, 2013). On rare occasions, they cause outbreaks in adults, but more often cause single cases of mild gastroenteritis in children. Astroviruses are often detected together with other gastrointestinal viruses, especially rotaviruses (Glass et al., 1996; Monroe et al., 2001). Astroviruses are spread predominantly through the fecal-oral route but can also be transmitted through contaminated food and water. Astroviruses are endemic throughout the world, with a winter seasonality in temperate climates and a higher prevalence during the rainy season in tropical regions. Asymptomatic infections occur in neonates and young children, especially in nurseries, childcare centers, and hospitals (Bresee et al., 1999; Caul, 1996a,b). Currently, no astrovirus vaccine is available. After infection, immunity against astrovirus lasts for several years, and by adulthood, most people contract very few symptomatic infections. Astrovirus infection can be prevented by frequent hand washing, disinfection of contaminated surfaces, prompt washing of soiled clothes, and avoidance of consumption of contaminated food or water. In addition, disinfection of contaminated fomites is important to stop transmission (Bosch et al., 2014).

Sapovirus

History

Sapovirus was first detected in human diarrheic stool samples in 1976 in the United Kingdom using EM (Madeley and Cosgrove, 1976). A year later, the virus was detected in an outbreak of gastroenteritis in an orphanage in Sapporo, Japan (Chiba et al., 1979). The virus was soon recognized as a novel etiology of diarrhea infection in both humans and animals (Nakata et al., 2000; Oka et al., 2015; Saif et al., 1980).

Morphology, structure, and nomenclature

Sapoviruses are small round viruses with a diameter of approximately 30–40 nm. They are morphologically distinct from other enteric viruses because of their characteristic star-of-David morphology and depression on the surface, formed by 32 cups or “calices,” visible under EM (Madeley, 1979; Oka et al., 2015; Roingear, 2008; Saif et al., 1980). Sapoviruses are non-enveloped, linear, positive-sense, single-stranded RNA viruses. The genome is approximately 7.1–7.7 kb in size with a poly(A) tail at the 3′-end and a genome-linked viral protein (VPg) covalently attached at the 5′-end. The virus has a $T = 3$ icosahedral symmetry, and the capsid consists of 180 capsid proteins (Oka et al., 2015). The genome is organized into two ORFs. ORF-1 encodes the nonstructural proteins (NS1–NS5 and NS6–NS7), as well as the major capsid protein, VP1, while ORF-2 encodes the minor capsid protein, VP2 (Miyazaki et al., 2015; Oka et al., 2015; Okada et al., 2006). Sapovirus VP1 capsid protein can be separated into several domains: the N-terminal variable region (NVR), N-terminal region (N), central variable region (CVR), and C-terminal region (C) (Fig. 11) (Oka et al., 2015).

Sapoviruses belong to the genus *Sapovirus* in the family *Caliciviridae* (Mayo, 2002). They have been detected not only in humans, but also in pigs, minks, dogs, sea lions, bats, chimpanzees, and rats (Oka et al., 2016). Sapoviruses are genetically highly diverse and classified into 19 genogroups (G) based on complete VP1 protein sequences (Yinda et al., 2017). Strains that infect humans belong to four genogroups (GI, GII, GIV, GV) (Barer, 2011; Oka et al., 2015; Scheuer et al., 2013). These viruses have distinctive conserved amino acid sequences in NS3 (GAPGIGKT), NS5 (KGKTK and DDEYDE), NS6 (GDCG), NS7 (WKGL, KDEL, DYSKWDST, GLPSG, and YGDD), and VP1 (PPG and GWS) (Oka et al., 2015).

Replication and pathogenesis

Due to the lack of a cell culture model, the replication cycle of sapoviruses has not been determined, yet; however, it is thought that, like other members of the family *Caliciviridae*, replication occurs in the cytoplasm (Oka et al., 2015).

Clinical manifestation

The main clinical symptoms of sapovirus infection include vomiting, diarrhea, nausea, abdominal cramps, chills, headache, myalgia, and malaise, all of which are indistinguishable from noroviruses. Although hospitalization has been reported, most sapovirus symptoms are self-limiting and patients usually recover within 1–4 days (Oka et al., 2015).

Diagnostic testing

Laboratory diagnosis of sapovirus relies on detection of viral RNA by real-time RT-PCR assay (Nagai et al., 2020; Oka et al., 2006, 2015; Saif et al., 1980). Sapoviruses can also be detected using of the commercially available multi-enteric pathogen assays such as the TaqMan Array Card (Liu et al., 2013) and Film Array Gastrointestinal Panel (Reddington et al., 2014).

Epidemiology, transmission, prevention, and control

Sapovirus infections are increasingly detected because of the increased use of the multi-enteric pathogen panels and are known to cause disease outbreaks in people of all age groups, including the elderly; persons in crowded or congregate living settings (such as

Fig. 11 A schematic diagram of the sapovirus genomic organization. This diagram shows two open reading frames, ORF1 and ORF2, as well as predicted viral nonstructural proteins and capsid proteins. Nonstructural proteins NS1, NS2, NS3 [NTPase], NS4, NS5 [VPg], NS6–NS7 [protease–RNA-dependent RNA polymerase (RdRp)], and the major capsid protein (VP1) are encoded by ORF1. ORF2 encodes VP2, the minor capsid protein. The following amino acid or nucleotide motifs are also shown and conserved among known sapoviruses: GXPGXGKT, PL (N/D) CD, and WDE (F/Y) D of NS3, KGKXX and XDEYXX of NS5, GDCG of NS6, WKGL, KDEL, DYSXWDST, GLPSG, and YGDD of NS7, PPG and GWS of VP1, and the first three nucleotides (GTG) at the 5′-end. The first five amino acids of NS1 (M [A/V] S [K/R] P) and around the NS7–VP1 cleavage site (FEME/G, where the slash indicates the putative cleavage site by viral protease NS6) are shown and are conserved among GI–GV, GVIII, and GXIII sapoviruses. From Oka T, Lu Z, Phan T, Delwart EL, Saif LJ, and Wang Q (2016) Genetic characterization and classification of human and animal Sapoviruses. *PLoS One* 11(5): e0156373.

daycares or assisted living facilities) may be especially vulnerable to outbreaks (Burke et al., 2021; Hansman et al., 2006, 2007; Lee et al., 2012; Oka et al., 2015; Page et al., 2016; Platts-Mills et al., 2018; Sanchez et al., 2018; Vielot et al., 2021). Although sapovirus gastroenteritis is generally mild, severe cases have been reported (Robinson et al., 2002; Vielot et al., 2021). The viruses can be transmitted from person to person through including contaminated materials/surfaces, or through contaminated food and drinking water (Oka et al., 2015). Like norovirus, sapovirus is probably transmitted efficiently via aerosol during vomiting. Currently, there are no vaccines or antiviral drugs available to prevent or treat sapovirus infections.

Acknowledgments

We would like to thank Ms. Mary Ann Hall, Ms. Claire Mattison, Ms. Anita Kambhampati and CDC Viral Gastroenteritis Branch for critical review of the book chapter.

Introduction

Both yeasts and filamentous fungi may infect the gastrointestinal (GI) tract, and are a particular risk for immunocompromised patients such as organ transplant recipients, patients receiving chemotherapy or immunomodulator therapy, and individuals with AIDS and other immune compromising conditions (Enoch et al., 2017; Pagano et al., 2017; Gavalda et al., 2014; Lionakis, 2019). As the number of patients with solid organ and bone marrow transplants and on immunosuppressive therapy has increased over the past few decades, so have invasive fungal infections (Antinori et al., 2016), and the endemic mycoses are one of the most significant infectious causes of morbidity and mortality in this population (Malcolm and Chin-Hong, 2013; Ellis, 2001; Fleming et al., 2002). Other risk factors for invasive fungal infections include repetitive abdominal surgeries, widespread use of antimicrobial agents, intrusive vascular lines, diabetes, total parenteral nutrition, neonatal prematurity, and advancing age (Enoch et al., 2017; Pagano et al., 2017; Gavalda et al., 2014; Lionakis, 2019). Although gastrointestinal fungal infections occur most commonly in immunocompromised patients, virtually all of the fungi discussed in this chapter can cause infections in immunocompetent persons as well. Knowledge of the patient's geographic and/or travel history may be very helpful in evaluating these cases.

Signs and symptoms of gastrointestinal fungal infections are often similar, regardless of the type of fungus. Esophageal fungal infections typically present with odynophagia and dysphagia, whereas gastric and intestinal infections may present with diarrhea, vomiting, melena, frank GI bleeding, abdominal pain, and fever. It is important to note that although fungal infections of the GI tract are often a part of a disseminated disease process, gastrointestinal symptoms and signs may be the presenting manifestations. Although *Candida* and *Aspergillus* species have historically represented the majority of fungi diagnosed in immunocompromised patients (Parize et al., 2012; Schwesinger et al., 2005), other fungi are emerging as more commonly encountered pathogens, such as *Fusarium* and the phaeohyphomycoses (Fleming et al., 2002; Arcobello and Revankar, 2020).

General principles of diagnosis

Despite advances in laboratory technology, particularly in the areas of serologic and molecular testing, the recognition, diagnosis, and classification of fungal infections in the immunocompromised patient population remains challenging. Tissue biopsy remains one of the most important tools available in the diagnosis of fungal infections, as fungal cultures may require days to weeks for adequate growth and analysis, and molecular assays may also have longer turnaround times. In addition, cultures are often not obtained as often as pathologists might wish or expect. The surgical pathologist can play an important role in both detecting the organism and identifying it, based on characteristic morphologic features (Guarner and Brandt, 2011; Procop and Pritt, 2018). Organisms may be identifiable on routine hematoxylin and eosin (H&E) stained sections, particularly in heavy infections, but Gomori methenamine silver (GMS) and periodic acid Schiff (PAS) stains remain invaluable diagnostic aids as they highlight most fungal elements and allow for enhanced microscopic identification. It is often possible to at least presumptively identify fungi based on morphologic features, particularly in cases of infection by *Candida* spp., the Mucorales, and the endemic dimorphic fungi (Lamps, 2012) (Tables 1 and 2). Similarly, *Aspergillus* spp. and similar-appearing fungi (e.g., *Fusarium* and other hyaline fungi with regularly-septate hyphae) can usually be differentiated from the Mucorales based on morphologic features; however, there is significant overlap in morphologic features among *Aspergillus* spp. and the *Aspergillus*-like fungi, and other techniques are required for definite identification (Guarner and Brandt, 2011; Lamps, 2012). It is also important to note that fungi exposed to antifungal therapy or ambient air may produce bizarre and unusual forms, and these may complicate the morphologic identification. Fungal infection should be strongly considered in any immunocompromised patient with ischemic lesions of the gastrointestinal tract, particularly ischemic lesions of the stomach; because of its rich blood supply, the stomach is not usually affected by ischemia due to atherosclerosis.

Identification of the specific genus is necessary because antifungal therapy may differ based on the involved organism, and therefore culture or molecular assays such as nucleic acid amplification testing (NAAT) and broad-range fungal sequencing may be required (Guarner and Brandt, 2011; Lamps, 2012). Culture provides the ability to perform antifungal susceptibility testing, results of which can vary significantly for some species (e.g., *Candida*), and which have growing importance in treatment of mold infections as well (Procop and Pritt, 2018).

Most diagnostic assays are based on detecting fungal cell wall elements and/or their antibodies in host tissue and body fluids. Nucleic acid amplification tests (NAATs) such as PCR are highly sensitive and specific, but cannot differentiate fungal colonization from true invasion. Thus, the results of NAATs must be correlated with the histopathologic findings whenever possible. Immunohistochemical (IHC) and in situ hybridization (ISH) tests may aid in this regard as they are performed directly on the FFPE tissue and can be viewed in the context of the histopathologic features. However, these tests suffer from cross-reactivity between fungal species and are not widely available. This is a promising area of active clinical research.

Other non-invasive fungal diagnostics that can complement a histologic diagnosis include antibody- and antigen-based detection tests. Urine antigen testing is particularly useful for endemic fungi such as *H. capsulatum*, and the combination of antigen testing with antibody testing through enzyme immunoassay (EIA), immunodiffusion and/or complement fixation increases the overall diagnostic yield. As with IHC and ISH, fungal antigen and antibody tests exhibit significant cross-reactivity among different fungal species, and thus need to be interpreted in the context of other test results.

Table 1 Morphologic features of filamentous fungi involving the gastrointestinal tract.

Organism (Disease)	Primary Geographic Distribution	Morphologic Features	Host Reaction	Major Differential Diagnoses
<i>Aspergillus</i> species (Aspergilliosis)	Worldwide	Hyphae- Septate Uniform width Branching-Regular Acute angles Conidial head formation in cavitary lesions	Ischemic necrosis with angioinvasion Acute inflammation Occasionally granulomatous	Mucorales, <i>Fusarium</i> spp., <i>Scedosporium</i> species complex (include fungus formerly known as <i>Pseudallescheria boydii</i>)
<i>Candida albicans</i> ; <i>Candida</i> spp. other than <i>C. glabrata</i> (Candidiasis); See also Table 2.	Worldwide	Mixture of budding yeast and pseudohyphae; occasional septate hyphae	Usually suppurative, with variable necrosis and ulceration Occasionally granulomatous	Occasionally <i>Aspergillus</i> , Also dematiaceous fungi (particularly if marked pleomorphism)
Mucormycores (Mucormycosis; older term = zygomycosis)	Worldwide, associated with diabetics more than any other mycosis	Thin-walled, pauciseptate, ribbon-like hyphae with thin walls and haphazard branching	Occasional angioinvasion Similar to <i>Aspergillus</i> spp.	<i>Aspergillus</i> spp., <i>Basidiobolus ranarum</i>
<i>Basidiobolus ranarum</i> (Basidiobolomycosis)	Saudi Arabia, Africa, Parts of Asia; Arizona	Similar to the Mucorales; fewer organisms, "cellophane ball" appearance	Eosinophilia, necrosis, granulomas, Splendore-Hoeppli reaction to organisms	Mucorales
<i>Fusarium</i> spp. (Fusariosis)	Worldwide	Similar to <i>Aspergillus</i> spp.; hyphae may be constricted at sites of origin	Similar to <i>Aspergillus</i> spp.	<i>Fusarium</i> spp., <i>Scedosporium</i> species complex

Table 2 Characteristics of yeasts involving the gastrointestinal tract.

Organism (Disease)	Primary Geographic Distribution	Histology
<i>Histoplasma capsulatum</i> (Histoplasmosis)	Ohio River Valley/Lower Mississippi River (North America); East Southern Cone (South America)	Small, round to oval yeast (2–4 μ m) with narrow based budding; "halo" effect
<i>Histoplasma duboisii</i> (African histoplasmosis)	Central Africa	Oval thick-walled yeast, 8–15 μ m, with narrow-based budding
<i>Talaromyces</i> (formerly <i>Penicillium</i>) <i>marneffei</i>	Southeast or Far East Asia	Small, round to oval yeast (2–5 μ m), occasional elongated forms; no budding, division by septation planes
<i>Cryptococcus neoformans/C. gattii</i>	Worldwide distribution	Small, round to oval yeast (2–20 μ m) with narrow based budding; pleomorphic in size; "soap bubble" gross appearance
<i>Candida albicans</i> ; <i>Candida</i> spp. other than <i>C. glabrata</i> (Candidiasis); See also Table 1.	Worldwide distribution	Mixture of budding yeast (5–8 μ m) and pseudohyphae; occasional septate hyphae
<i>Candida glabrata</i>	Worldwide distribution	Budding yeast without hyphae; may be extracellular
<i>Pneumocystis jirovecii</i> (pneumocystosis)	Worldwide distribution	4–6 μ m spherules, typically extracellular, with cup or crescent shapes when collapsed, Paired comma-shaped internal structure
Microsporidia (Microsporidiosis)	Worldwide distribution	0.7–4 μ m spores; size varies by genus

Finally, there are two commonly-used serum-based detection methods that detect components of the fungal cell wall that can aid in the diagnosis of invasive fungal infection. The galactomannan assay detects a component of the *Aspergillus* cell wall that is released during growth, and thus is helpful in diagnosing invasive aspergilliosis (Pfeiffer et al., 2006). The beta (1,3) D glucan assay is another test that detects fungal antigen that is a component of the cell wall of most fungi (Karageorgopoulos et al., 2011). Thus, this test is positive in many disseminated fungal infections, with important exceptions including the Mucorales, *Cryptococcus* spp. and *Blastomyces* spp.

When fungal infection is in the differential diagnosis prior to obtaining tissue, a separate specimen should be submitted for fungal stain and culture. Consideration should also be given to setting a piece of fresh tissue aside for targeted or broad range

molecular tests. The clinical microbiology laboratory generally employs primary fluorescence stains such as calcofluor white to perform a fungal smear, which allow for rapid and relatively sensitive screening of the specimen while awaiting the more sensitive culture results. If a fungal infection is an unexpected finding and fresh tissue is not available, PCR can be performed on FFPE tissue. These assays are either species-specific for common pathogens such as *H. capsulatum* and *Pneumocystis jirovecii*, or consist of broad-range assays that use primers that anneal to conserved DNA regions and sequencing to identify the genus and species. Unfortunately, the analytical sensitivity of these assays is limited by the degradation of nucleic acids by formalin, and thus having stored fresh tissue for molecular analysis is desirable. Molecular tests are often expensive, have relatively long turnaround times (several days), and are only available at specialized reference laboratories.

A detailed discussion of the major mycoses affecting the gastrointestinal tract is presented in the following sections. Other fungal infections that occasionally involve the gastrointestinal tract, but are not discussed in detail here, the phaeohyphomycoses (dematiaceous, or naturally pigmented, fungi), *Coccidioides immitis*/*C. posadasii*, *Blastomyces dermatitidis*/*B. gilchristii*, and *Paracoccidioides brasiliensis* (South American blastomycosis), which can mimic chronic idiopathic inflammatory bowel disease both clinically and radiographically (Arcobello and Revankar, 2020; Weatherhead et al., 2015; Martinez et al., 1979; McKenzie and Khakoo, 1985).

Aspergillus species (aspergillosis)

Aspergillus is a genus of ubiquitous non-pigmented (hyaline) environmental fungi. Infection of the gastrointestinal tract occurs almost exclusively in immunocompromised patients, particularly those with prolonged neutropenia, and thus bone marrow transplant recipients are at particular risk for invasive aspergillosis (Pagano et al., 2017; Gavalda et al., 2014; Malcolm and Chin-Hong, 2013; Ellis, 2001; Prescott et al., 1992). Aspergillosis in immunocompromised hosts can be a medical emergency leading to rapidly life-threatening disease and requiring urgent treatment. Disease in immunocompetent hosts is uncommon.

Aspergillus fumigatus and *A. flavus* are the most common pathogens, but several other species including *A. niger*, *A. terreus*, *A. versicolor*, and *A. nidans* may also cause human disease (Centers for Disease Control and Prevention, 2018). Infection is acquired almost exclusively through inhalation of microscopic airborne spores, leading to primary infection of the respiratory tract, with the potential for subsequent hematogenous dissemination to other organs in immunocompromised hosts (Prescott et al., 1992; Eggimann et al., 2006). Extrapulmonary involvement has been reported in 25–60% of cases of invasive aspergillosis, and is seen almost entirely in the context of primary pulmonary infection (Eggimann et al., 2006). Primary intestinal aspergillosis is rarely, presumably secondary to ingestion of infectious spores (Prescott et al., 1992; Eggimann et al., 2006).

Clinical features

The bowel (particularly colon) is the most frequent site of gastrointestinal involvement, followed by the esophagus and stomach. Multiple sites of concomitant involvement are common. Aspergillosis is much less frequently seen in the esophagus compared to candidiasis. Most patients have clinical or radiologic features of concomitant pulmonary disease (Lamps, 2012; Centers for Disease Control and Prevention, 2018; Eggimann et al., 2006). Common intestinal symptoms are fever, vomiting, abdominal pain, diarrhea, and GI bleeding (Lamps, 2012). First line therapy of invasive disease is voriconazole (Centers for Disease Control and Prevention, 2018).

Gross findings

The characteristic histologic lesion of aspergillosis is a nodular infarction, which may be transmural, consisting of a zone of ischemic necrosis centered on blood vessels containing fungi. These nodular infarctions may produce mucosal “target lesions” with a central necrotic zone surrounded by a ring of hemorrhage (Fig. 1). The surrounding mucosa is commonly erythematous, edematous, and ulcerated (Lamps, 2012). Occasionally an inflammatory mass (aspergilloma) may be seen (Ibrahim, 2000).

Microscopic findings

Aspergillus is highly angioinvasive, a feature that results in many of the characteristic morphologic findings. As noted above, transmural infarction of the bowel wall is common, and fungal hyphae often extend outward from the infarct in parallel or radial arrays, with associated ischemic necrosis (Fig. 2) (Guarner and Brandt, 2011; Lamps, 2012). Depending on the extent of immune compromise, the associated host response may range from minimal inflammation to marked neutrophilic infiltrates (Lamps, 2012) (Fig. 3). Granulomatous inflammation may be present as well. The typical hyphae of *Aspergillus* are narrow (3–12 µm diameter), uniform, and regularly septate, classically with parallel walls and acute angle, dichotomous branching (Fig. 4). Occasional atypical enlarged/bulbous forms are commonly seen in tissue.

Differential diagnosis

Several hyaline molds, such as *Fusarium*, *Paecilomyces*, and *Scedosporium* species, have nearly identical histologic appearance to that of *Aspergillus*, so that definite identification cannot be made from tissue morphology alone (Guarner and Brandt, 2011; Procop and

Fig. 1 This autopsy specimen shows a stomach with the characteristic “target lesion” of *Aspergillus* infection. The nodular infarction consists of a central necrotic zone surrounded by a ring of dark brown hemorrhage.

Fig. 2 A nodular infarction with overlying ischemia in the stomach of a bone marrow transplant patient.

Pritt, 2018). The only exception to this is when *Aspergillus* spp. fruiting heads are seen in tissue; this is a rare occurrence that is typically seen when the infection is contiguous with an airspace. Given the limitations of morphology, suggested phrasing in the pathology report is, “Narrow, regularly-septate hyphae with acute angle branching. Differential diagnosis includes *Aspergillus* and similar sp. Culture or molecular identification is required for definite diagnosis.” The tissue reaction of *Aspergillus* spp. and the Mucorales can certainly mimic each other, but in contrast to *Aspergillus*, the Mucorales have broad, ribbon-like, pauciseptate hyphae with irregular walls, which branch randomly at various angles.

Fig. 3 Fungi occlude a small vessel in the wall of the bowel, with associated neutrophilic inflammation and necrosis.

Fig. 4 Typical hyphae of *Aspergillus* spp. are narrow and regularly septate, with parallel walls and acute angle, dichotomous branching. These fungi are seen within a small vessel in the bowel wall (GMS stain).

Mucorales (mucormycosis)

The Mucorales is an order within the Zygomycetes comprising multiple genera that cause human mucormycosis (formerly zygomycosis) (Guarner and Brandt, 2011; Centers for Disease Control and Prevention, 2018). Like *Aspergillus*, the mucorales are ubiquitous environmental fungi that rarely cause disease in immunocompetent hosts, but can cause serious, life-threatening disease in immunocompromised hosts (Centers for Disease Control and Prevention, 2018). *Rhizopus* spp. are the most common cause of

mucormycosis, but several other genera including *Mucor*, *Rhizomucor*, and *Lictheimia* also cause disease (Guarner and Brandt, 2011). Although *Aspergillus* species have long been recognized as the most commonly encountered filamentous fungi in the immunocompromised patient population, for reasons that remain poorly understood, the incidence of mucormycosis is increasing, particularly in patients with diabetes, hematologic malignancies, and bone marrow transplants (Dictar et al., 2000). Mucormycosis is associated with poorly-controlled diabetes and other causes of metabolic acidosis, deferoxamine therapy, organ or bone marrow transplant, neutropenia, skin and soft tissue breakdown, intravenous drug use, neonatal prematurity, and malnourishment. Interestingly, HIV/AIDS does not appear to be a risk factor for this infection. The mortality rate is quite high (over 40% in general, and even higher in patients with hematologic malignancies and those status post bone marrow transplant). Gastrointestinal mucormycosis is an uncommon form of infection seen primarily in the setting of severe immune compromise and concomitant pulmonary infection (Centers for Disease Control and Prevention, 2018; Hosseini and Lee, 1998; Kahn, 1963; Thomson et al., 1991).

Clinical features

Gastrointestinal mucormycosis (Hosseini and Lee, 1998; Kahn, 1963; Thomson et al., 1991) is relatively uncommon, but often fatal. Patients with gastrointestinal involvement commonly present with nausea, vomiting, abdominal pain, and occasionally, gastrointestinal bleeding (Centers for Disease Control and Prevention, 2018). In neonates, the presentation may resemble that of necrotizing enterocolitis. Treatment is usually with lipid formulations of amphotericin B (Centers for Disease Control and Prevention, 2018). The Mucorales do not respond to voriconazole, an agent commonly used for prophylaxis and treatment of aspergillosis, which underscores the importance of proper fungal identification.

Gross findings

Any level of the GI tract can be involved, but gastric and colonic involvement are most common. The gross findings are similar to those of aspergillosis, with ulceration and infarction being common findings. Ulcers may be large with irregular, rolled edges, mimicking malignancy (Lamps, 2012). The Mucorales may also superinfect previously ulcerated tissues.

Microscopic findings

As with aspergillosis, nodular infarction with angioinvasion is a characteristic microscopic finding of mucormycosis (Lamps, 2012). The inflammatory response is variable, but neutrophils are usually prominent. The hyphae are usually visible with H&E, particularly in areas of necrosis (Fig. 5). The hyphae differ from those of *Aspergillus* spp., as they are pauciseptate, with irregular diameters ranging from 5 to 20 μ m (Guarner and Brandt, 2011). The appearance of optically clear centers is often seen on cross-section (Fig. 6). The hyphal walls are very thin and easily collapse during histologic processing, giving the appearance of “crumpled cellophane” (Guarner and Brandt, 2011; Lamps, 2012). Branching occurs at various angles including acute and right angles (Procop and Pritt, 2018; Lamps, 2012).

Differential diagnosis

The Mucorales can often be differentiated morphologically from the uniformly narrow, regularly septate molds such as *Aspergillus* by their broad, irregular, crumpled, pauciseptate hyphae (Guarner and Brandt, 2011).

A rare entity that must also be considered in the differential diagnosis is gastrointestinal infection with *Basidiobolus ranarum*, a fungus in the order Entomophthorales (see below).

Basidiobolus ranarum (basidiobolomycosis)

B. ranarum is a zygomycete of the order Entomophthorales, which are closely related to the Mucorales, both being members of the Zygomycetes; however, they have very different pathogenic potentials. Basidiobolomycosis is a chronic infection seen primarily in immunocompetent patients. Risk factors include pediatric age group, peptic ulcer disease, diabetes, pica, ranitidine use, and living in an endemic area. Of note, unlike many of the other filamentous fungi, typical causes of immunocompromise such as neutropenia, HIV/AIDS, and organ transplantation are not risk factors for this infection. Infection by this world-wide soil saprophyte was originally described in Africa, Saudi Arabia, and Southeast Asia, but has recently gained attention in the United States, primarily in Arizona (Centers for Disease Control and Prevention (CDC), 1999; Yousef et al., 1999; Lyon et al., 2001).

Clinical features

Unlike the skin and subcutaneous infection in which this organism was originally described, *B. ranarum* has typically affected the gastrointestinal tract in the United States. Abdominal pain is the most common presenting symptom (Centers for Disease Control and Prevention (CDC), 1999; Yousef et al., 1999; Lyon et al., 2001).

Fig. 5 This gastric biopsy with invasive Mucorales infection shows ischemic-appearing mucosa with associated neutrophils and an exudate (top of image) that contains fungi (A). Invasive organisms are also seen in the mucosa (B, arrow).

Fig. 6 The hyphae of the Mucorales are broad and ribbon-like, with optically clear centers on cross section. They are pauciseptate with variable diameters, and branch at random angles.

Gross findings

The colon and rectum are most frequently involved, followed by the small bowel and stomach. Gastrointestinal infections may mimic malignancy or chronic idiopathic inflammatory bowel disease clinically, and many patients have presented with pericolic masses that are worrisome for colon cancer (Nemenqani et al., 2009).

Microscopic findings

The hyphae are very similar to those of the mucorales, but the tissue reaction is quite different, featuring intense granulomatous inflammation with prominent eosinophils, neutrophils, necrosis, and fibrosis (Guarner and Brandt, 2011) (Fig. 7). The hyphae are commonly associated with peripheral bright pink Splendore-Hoeppli reaction (Fig. 8).

Differential diagnosis

Although the fungi themselves are morphologically similar to those that cause mucormycosis, there are typically fewer of them in a given tissue section. In addition, *B. ranarum* may have more pronounced “cellophane-ball” or crumpled appearance (Fig. 9). *Basidiobolus* is not angioinvasive, in contrast to the Mucorales, and mucormycosis does not have prominent eosinophilia or Splendore-Hoeppli reaction to organisms.

Fig. 7 This section of a colonic wall mass shows necrosis and granulomatous inflammation with giant cells and striking associated eosinophilia.

Fig. 8 The fungi have associated bright pink Splendore-Hoeppli protein deposits on their walls, which highlight them within the granulomas. Note the numerous eosinophils.

***Candida* species**

The gastrointestinal tract is a major portal for disseminated candidiasis, as *Candida* often superinfects ulcers that develop from other causes. *C. albicans* is most commonly isolated of the *Candida* species, but *C. tropicalis* and *C. (Torulopsis) glabrata* may produce similar clinical and pathologic manifestations. Other non-*albicans* species (such as *C. krusei* and *C. parapsilosis*) are also emerging as important causes of invasive fungal infection. Common risk factors for invasive candidiasis include immunosuppression, chemotherapy, corticosteroids, and major abdominal surgery (Enoch et al., 2017; Pagano et al., 2017; Gavalda et al., 2014; Lionakis, 2019; Antinori et al., 2016).

Fig. 9 *B. ranarum* has a similar morphologic appearance as the Mucorales, but there are typically fewer organisms present in the tissue, and they are commonly surrounded by the Splendore-Hoeppli protein. Note the thin walls with a crumpled appearance, and rare septa (A, GMS stain). Some fungi have a “cellophane ball” morphology (B, GMS stain).

Clinical features

Candida is the most common infection of the esophagus, but may infect any level of the GI tract (Prescott et al., 1992; Kondo and Terada, 2017; Hoversten et al., 2018; Hissong et al., 2020).

Gross findings

Esophageal infection typically features white plaques that easily scrape away to reveal ulcerated mucosa underneath (Fig. 10). The gross features of candidiasis in the stomach and intestines are variable and include ulceration, pseudomembrane formation, and inflammatory masses (Prescott et al., 1992) (Fig. 11). The ulcers are often multiple, irregular, and hemorrhagic, and may be confluent in advanced cases. Deep linear ulcers also have been described. If vascular invasion is prominent, the bowel may appear infarcted. Involvement may be diffuse or segmental.

Fig. 10 This endoscopic photograph from an AIDS patient shows white plaques throughout the esophagus. Courtesy Dr. Rhonda Yantiss.

Fig. 11 This gastric specimen with invasive *Candida* infection, from an autopsy, shows variably sized ulcerations with yellow plaques (arrow).

Microscopic findings

The associated inflammatory response ranges from minimal (especially in immunocompromised patients) to marked with prominent neutrophilic infiltrates, abscess formation, erosion/ulceration, and necrosis (Fig. 12). When pseudomembranes are present, they are composed of a mixture of yeast, necrotic debris, and fibrin. Granulomas are occasionally present. Numerous intra-epithelial neutrophils in the squamous mucosa of the esophagus is a common finding in esophageal candidiasis, and should provoke the use of fungal stains if organisms are not appreciated on H&E. Fungi may invade any level of the gut wall, and invasion of mucosal and submucosal blood vessels is sometimes a prominent feature (Lamps, 2012; Prescott et al., 1992).

C. albicans, *C. tropicalis* and species other than *C. glabrata* produce a mixture of budding yeast forms intermingled with pseudohyphae and occasional true hyphae (Fig. 13). *C. glabrata* features tiny budding yeast forms similar to *H. capsulatum*, but does not produce hyphae or pseudohyphae (Fig. 14).

Differential diagnosis

Grossly, intestinal candidiasis may mimic other inflammatory process including chronic idiopathic inflammatory bowel disease, pseudomembranous colitis, and ischemic colitis. As above, fungal stains should be strongly considered in any immunocompromised patient with ischemic lesions of the gastrointestinal tract.

It is important to morphologically differentiate between invasive candidiasis and superficial colonization, as *Candida* is capable of colonizing benign ulcers and mucosal surfaces without invasion. In the esophagus, care should be taken to avoid confusing oral contamination by *Candida* for true invasive *Candida* esophagitis. In invasive candidiasis, fungi should be present within the squamous epithelium, often (but not always) with associated acute inflammation (Fig. 15) (Hissonig et al., 2020).

Fig. 12 Esophageal candidiasis typically features neutrophilic inflammation with acantholysis or sloughing of the superficial squamous mucosa (A). This esophageal biopsy contains an exudate consisting of yeast, sloughed epithelial cells, and inflammation (B).

***Cryptococcus* species (cryptococcosis)**

Cryptococcus is a ubiquitous environmental fungus that is a rare but important cause of gastrointestinal infection (Centers for Disease Control and Prevention, 2018). The two most common species are *C. neoformans* and *C. gattii*. *C. neoformans* is found throughout the world and causes disease primarily in immunocompromised hosts; it is a saprophytic organism, commonly associated with pigeons. *C. gattii* is found in the tropics, subtropics, and Pacific Northwest, and associated with eucalyptus trees; it may infect both immunocompromised and immunocompetent hosts (Centers for Disease Control and Prevention, 2018). Infection is acquired through inhalation of fungal spores, resulting in a primary respiratory infection in susceptible individuals (Centers for Disease Control and Prevention, 2018). Both *C. neoformans* and *C. gattii* are capable of disseminating from the lungs to other organs (Centers for Disease Control and Prevention, 2018), and have a predilection for the central nervous system.

Gastrointestinal involvement occurs almost exclusively in immunocompromised hosts and is due to dissemination from a primary respiratory source; however, rare cases of GI involvement in immunocompetent hosts, and of primary intestinal cryptococcosis, and have been reported (Melato and Gorji, 1998; Washington et al., 1991; Harris et al., 2011).

Fig. 13 The morphology of *Candida albicans* is a mixture of budding yeast and pseudohyphae, with occasional true hyphae as seen in this image (A, GMS stain). Fig. (B) (Gram stain) shows pseudohyphae, from which yeasts bud directly (arrow).

Clinical features

Most patients have clinical or radiographic evidence of pulmonary and central nervous system involvement (Lamps, 2012; Washington et al., 1991). Symptoms of intestinal involvement include abdominal pain and distension. Treatment varies with the severity of disease, and severe extra-pulmonary disease is treated with liposomal amphotericin B plus flucytosine (Perfect et al., 2010).

Gross findings

Any part of the gastrointestinal tract may be involved, but the colon is the most frequently involved site, followed by the esophagus. Endoscopic lesions include nodules and ulcers, sometimes associated with thick white exudates (Lamps, 2012; Washington et al., 1991). However, the mucosa is normal in many cases, even when deeply invasive organisms are present, as the organisms are often

Fig. 14 Unlike the other *Candida* species, *Candida glabrata* is only present as small, oval-shaped, yeasts with narrow-based budding, and thus can be difficult to differentiate from *Histoplasma capsulatum*. Unlike *H. capsulatum*, *C. glabrata* is usually visible on H&E (left side of image), is commonly extracellular, and may have an associated suppurative host response. Thus it is important to carefully examine the H&E-stained slide as well as the GMS (right side of image) to differentiate these 2 morphologically-similar fungi.

Fig. 15 Some patients have invasive candidiasis (arrow), but no associated inflammation.

located within lymphatics. Inflammatory polypoid masses have been described rarely. In heavy infections with abundant mucopolysaccharide capsular material, small gelatinous pseudocysts may form which are visible grossly and radiologically as “soap bubble” lesions, particularly in the brain.

Microscopic findings

Histologically, the inflammatory reaction is variable and depends on the immune status of the host, ranging from a suppurative, necrotizing inflammatory reaction (Fig. 16) to virtually no reaction in profoundly immunocompromised hosts (Guarner and Brandt, 2011; Procop and Pritt, 2018; Lamps, 2012; Washington et al., 1991) (Fig. 17). Both superficial and deep involvement may

Fig. 16 *Cryptococcus neoformans* is seen within a giant cell in a granuloma (arrows). Note the non-staining "soap bubble" appearance associated with the organism, caused by the capsule.

Fig. 17 This liver biopsy from an AIDS patient contains innumerable *Cryptococcus* sp. within macrophages, but virtually no inflammatory reaction.

occur, and lymphatic involvement is common. In patients with some degree of native immunity, a granulomatous response may be seen with occasional formation of a mass lesion (cryptococcoma).

The two species are morphologically identical. The diagnostic feature is the presence of variably-sized (2–20 μm), round, intra- and extra-cellular yeasts within the mucosa and/or submucosa (Guarner and Brandt, 2011; Procop and Pritt, 2018; Lamps, 2012; Washington et al., 1991). Variation in size is a typical feature of cryptococcosis (Fig. 18). The yeasts typically have a non-staining halo corresponding to the presence of a mucopolysaccharide capsule, which may also be described as having a "soap bubble" appearance (Fig. 16). Yeasts divide by narrow-based budding. Rare pseudohyphae may also be seen (Procop and Pritt, 2018). The yeast capsule often stains deeply with mucin stains such as mucicarmine (Fig. 19) and Alcian blue, although capsule-deficient strains may be mucicarmine negative (Ro et al., 1987). The cell wall may also be highlighted using a Fontana-Masson stain (Fig. 20), although this varies widely by the stain formulation being used, and may stain other similar-appearing yeasts such as dematiaceous fungi (Guarner and Brandt, 2011; Procop and Pritt, 2018; Ro et al., 1987).

Fig. 18 GMS stain of *C. neoformans* highlights numerous yeasts with variation in size, and rare narrow-based buds (arrow).

Fig. 19 *Cryptococcus* spp. often, but not always stain with mucicarmine (left). Some strains are capsule deficient, and may be partially or entirely mucicarmine negative. In other cases, abundant mucin production forms mucicarmine-positive pools with deeply-staining yeasts within.

Differential diagnosis

The yeasts of *Cryptococcus* spp. can usually be differentiated from other yeasts by their variable size, capsule, and narrow-based budding (see Table 2). Other yeasts that infect humans do not have a true capsule, and thus its presence is diagnostic for *Cryptococcus*. It is important to note that the cell wall of *Blastomyces dermatitidis*, which only rarely infects the GI tract, may be faintly mucicarmine positive and should not be interpreted as evidence of a capsule. Features useful for differentiating *B. dermatitidis* from *Cryptococcus* spp. are the uniformly large size of the former (8–15 μm diameter) and thick refractile cell wall on H&E. *Histoplasma capsulatum* may also be in the differential diagnosis, particularly when only small forms are seen, but is more oval rather than round and lacks a capsule (see below). In addition, *H. capsulatum* does not stain with mucicarmine. In cases of capsular-deficient cryptococcosis, the cell wall will often still stain with Fontana-Masson (Ro et al., 1987).

Fig. 20 Cryptococcal cell walls will also stain with Fontana-Masson, including capsule-deficient strains.

***Histoplasma capsulatum* (histoplasmosis)**

Histoplasma capsulatum is a saprophytic fungus with a near-worldwide distribution (Centers for Disease Control and Prevention, 2018; Goodwin and Des Prez, 1978; Goodwin et al., 1980, 1981). *H. capsulatum* var. *capsulatum* is found in close association with river valleys in all continents except Antarctica, while *H. capsulatum* var. *duboisii* (a.k.a., *H. duboisii*) is found in Africa (Centers for Disease Control and Prevention, 2018). This section will focus on *H. capsulatum* var. *capsulatum*, which is the most common cause of intestinal histoplasmosis. *H. capsulatum* var. *capsulatum* is endemic to the central United States, especially within the Ohio, Missouri, and Mississippi river valleys; other endemic areas in the Western hemisphere include Mexico, Guatemala, Peru, and Venezuela. Histoplasmosis has been reported in many nonendemic areas as well.

H. capsulatum is a thermally-dimorphic fungus, growing as a mold in the environment (25 °C), predominantly in soil enriched with bird or bat droppings, and as a yeast in humans (36 °C). Infection is acquired primarily through inhalation of microscopic airborne microconidia, resulting in a primary pulmonary infection with the potential for dissemination to other organs. It has a marked affinity for dissemination through the mononuclear phagocyte system, and gastrointestinal tract involvement is seen in 70–90% of cases with disseminated infection (Lamps, 2012; Cappell et al., 1988; Yang et al., 2013). Most patients are profoundly immunocompromised, but intestinal histoplasmosis can rarely occur in immunocompetent patients, as well as in patients such as young children and the elderly, who may not have fully functional immune systems (Lamps, 2012; Cappell et al., 1988; Yang et al., 2013). Isolated gastrointestinal histoplasmosis has been reported rarely. It is the most common endemic mycosis in patients with AIDS, and has also been described in association with infliximab therapy, an anti-tumor necrosis factor alpha drug used in the treatment of Crohn's disease and rheumatoid arthritis.

Clinical features

Most patients will have clinical or radiographic evidence of pulmonary and disseminated disease (Cappell et al., 1988; Lamps et al., 2000), but patients may initially present with signs and symptoms of gastrointestinal illness, and do not always have concomitant pulmonary involvement. Notable presenting gastrointestinal symptoms include diarrhea, gastrointestinal bleeding, abdominal pain, dysphagia, nausea, vomiting, weight loss, and signs of small bowel obstruction (Lamps et al., 2000). The majority of patients are febrile, and many have had symptoms for weeks to months. Gastrointestinal bleeding and anorectal disease are more common in patients with AIDS and other immunocompromising conditions.

Gross findings

The ileum is the most common site of involvement, followed by colon, stomach, and esophagus; any portion of the gastrointestinal tract may be involved. Associated lymphadenopathy is common. The esophagus may also be impinged upon by mediastinal lymphadenopathy secondary to histoplasmosis, or by *Histoplasma*-associated mediastinal fibrosis. Ulcers are the most common gross lesion; they are often multiple, with annular raised borders, associated hemorrhage, and necrosis at the base. Nodules (often centered on lymphoid aggregates) and obstructive masses or strictures are also common. Often, a combination of lesions is present (Lamps et al., 2000).

Microscopic findings

Histologic findings include diffuse lymphohistiocytic infiltrates and nodules (Fig. 21A), usually involving the mucosa and submucosa, with overlying ulceration. In the ileum, these lesions are often associated with Peyer patches (Cappell et al., 1988; Lamps et al., 2000). In addition to histiocytes and lymphocytes, there may be numerous associated eosinophils, neutrophils, and plasma cells. Nonspecific ulceration and inflammation with numerous organisms present in the bowel wall may be seen as well. Discrete granulomas and giant cells are present in only a minority of cases (Fig. 21B). In contrast to gastrointestinal lesions, abdominal lymph nodes often show necrotizing granulomas. In immunocompromised patients or very young children, endoscopic findings may be normal, and large numbers of organisms may be seen with virtually no tissue reaction histologically.

H. capsulatum yeasts are small (2–5 µm) and ovoid with single small buds at the more pointed pole (Fig. 22), typically within histiocytes. Multiple organisms are often clustered within a macrophage. The yeasts may be extremely difficult to see on H&E, but can occasionally appear as small intracellular objects with a narrow surrounding clear zone or halo (Fig. 23). The halo (pseudo-capsule) results from the poorly-stained cell wall rather than the presence of a true capsule as seen with *Cryptococcus* spp. (Procop and Pritt, 2018). The yeasts exhibit narrow-based budding, which is best seen with GMS. Unlike other yeasts, *H. capsulatum* does not always stain well with PAS.

Differential diagnosis

The overall histologic picture of intestinal histoplasmosis is similar to that of other diffuse histiocytic processes such as Whipple's disease, malakoplakia and *Mycobacterium avium* complex infection. The presence of small intracellular yeasts allows these processes to be excluded, and narrows the differential to other yeast infections. The morphology of *H. capsulatum* is similar to that of *Cryptococcus* spp. (see above), but with uniformly small rather than variably-sized forms. Unlike *Cryptococcus* spp., *H. capsulatum* also lacks a capsule. Other small yeasts that may enter the differential include *Talaromyces* (formerly *Penicillium*) *marneffei* (usually patients from Southeast Asia) and *Candida glabrata*. *T. marneffei* can be differentiated by its lack of budding. *P. carinii* can also be differentiated by its lack of buds, as well as its internal structure, the fact that it is usually extracellular, and the commonly-seen "foamy cast" tissue reaction. *C. glabrata* is more difficult to differentiate, but causes a suppurative rather than histiocytic inflammatory reaction and is more easily visible on H&E (Fig. 14). The GMS appearance of *C. glabrata* is identical to that of *H. capsulatum*, so that culture or NAATs may be required to differentiate them (Procop and Pritt, 2018). Blastomyces is much larger and has broad-based buds and *Leishmania* spp., have a characteristic kinetoplast and are GMS negative. Erythrocytes and naked cell nuclei may mimic *Histoplasma* in sections overstained with GMS; comparison with H&E slides often helps to resolve this.

Clinically, the differential diagnosis for the inflammatory lesions of histoplasmosis includes idiopathic inflammatory bowel disease, sarcoidosis, and other infections. Obstructive masses may mimic neoplasia as well. GMS and/or PAS should easily identify organisms.

Several other laboratory methods are available for diagnosing histoplasmosis (Azar and Hage, 2017). Fungal cultures are the gold standard when positive, but are not useful for rapid diagnosis. Histoplasmin skin testing and serologic tests may be useful in immunocompetent adults, but are unreliable in immunocompromised patients, young children, elderly patients, and those with disseminated disease. Urine antigen detection may be helpful.

Talaromyces (formerly *Penicillium*) *marneffei*

T. marneffei is a dimorphic fungus that is endemic in Thailand, China, Hong Kong, Vietnam, and Indonesia. Patients with this infection who are encountered in Western countries have almost always either traveled to these areas or lived there (Ko et al., 1999; Borradori et al., 1994; Cooper and McGinnis, 1997). This infection is emerging as one of the most common opportunistic infections in Asian patients with AIDS (Borradori et al., 1994; Bulterys et al., 2013). Patients with who are not HIV positive usually have other immunocompromising conditions, such as hematologic malignancies, autoimmune diseases, malnutrition, or other debilitating conditions. It has rarely been described in immunocompetent persons. Dissemination can occur in a matter of a few weeks and be quickly fatal, especially in immunocompromised patients. Months of antifungal therapy may be required for effective therapy.

Clinical features

T. marneffei most commonly involves the lungs and liver, followed by the GI tract. Common presenting symptoms include fever, anemia, weight loss and skin lesions; diarrhea is common in patients with GI involvement (Ko et al., 1999). The mortality rate is very high, in large part due to delay in diagnosis and treatment.

Gross findings

Any level of the GI tract may be involved. Endoscopic findings include ulcers, erosions, and inflammatory masses (Ko et al., 1999).

Fig. 21 A nodular lymphohistiocytic infiltrate involves the mucosa and submucosa of the small bowel in a case of histoplasmosis (A). This patient on long term Humira developed a large ileal ulcer due to histoplasmosis. The arrows point to the germinal centers of lymphoid follicles comprising the Peyer's patches of the ileum. (B) Courtesy Dr. Joel Greenson.

Fig. 22 The yeasts of *Histoplasma capsulatum* are uniformly small, oval, and divide by narrow-based budding (GMS, arrows).

Microscopic findings

As with the other dimorphic fungi, *T. marneffei* grows as a yeast in humans and as a mold in the environment. The yeasts of *T. marneffei* infect the mononuclear phagocyte system, and multiply within histiocytes that enlarge to accommodate increasing numbers of organisms (Fig. 24). The inflammatory response may be granulomatous, suppurative, or mixed. As the lesions expand, necrosis predominates, and the macrophages may lyse and release free organisms (Cooper and McGinnis, 1997).

The organisms themselves are spherical to ovoid, and fill and distend the involved macrophages (Fig. 25). The fungi are typically small (2–5 μm) and are about the same size as *H. capsulatum*; however, occasional elongated and/or curved forms may be present, and these may measure up to 20 μm . Of note, *T. marneffei* does not bud, as they divide at their central septum by fission. Elongated forms with the central septum are sometimes referred to as “pill capsule” forms.

Differential diagnosis

The major organism in the morphological differential diagnosis is *H. capsulatum*, as both are typically intracellular and are of similar size (Cappell et al., 1988; Yang et al., 2013). As noted above, *H. capsulatum* yeasts divide by narrow-based budding at one pole, whereas *T. marneffei* do not bud. On H&E staining, *H. capsulatum* also often has a surrounding small “halo.” In addition, the areas in which these two yeasts are endemic are very distinct. *Cryptococcus* spp. (measuring 2–20 μm) are larger than the yeasts of *T. marneffei*, show much more variation in size, and also shows frequent narrow-based budding (Fig. 18). *Pneumocystis jirovecii* are also larger than *T. marneffei* (4–6 μm) and are round, but have cup or crescent shapes when collapsed. They lack the transverse septum of *T. marneffei*, and do not pack and distend macrophages. Many contain characteristic single or paired comma-shaped internal structures. *Candida glabrata* features tiny budding yeast forms of similar size to *T. marneffei*, but is extracellular and has frequent narrow-based budding (Fig. 14). *C. glabrata* also lacks the transverse septum of *T. marneffei*. The galactomannan assay for detection of *Aspergillus* infection will cross-react with *T. marneffei* (Dieterich et al., 1992), which may have utility as the organisms appear quite different in tissue.

Pneumocystis jirovecii (formerly *carinii*)

P. jirovecii has a life cycle that more closely resembles a protozoan, but over time there has been convincing molecular evidence indicating that it has greater homology with fungi. *P. carinii* pneumonia is a major cause of morbidity in the AIDS population, and extrapulmonary (including gastrointestinal) involvement is not uncommon. In addition to patients with AIDS, *P. jirovecii* infection has been occasionally reported in the context of organ transplant, hematologic malignancy, other immunodeficiency states, and steroid therapy. *P. jirovecii* infection has also associated with infliximab therapy, an immunosuppressive treatment for Crohn’s disease and rheumatoid arthritis (Dieterich et al., 1992; Kaur and Mahl, 2007). Risk factors for extrapulmonary infection include severe underlying immunodeficiency, overwhelming pulmonary infection, and aerosolized pentamidine prophylaxis for *Pneumocystis jirovecii* pneumonia (a.k.a. PJP).

Fig. 23 This colon biopsy contains a histiocytic infiltrate with numerous intracellular yeasts of *Histoplasma capsulatum* (A). The yeasts appear as small intracellular objects with a surrounding halo, a result of the poorly-stained cell wall (B). (A) Courtesy Dr. Maria Westerhoff. (B) Courtesy Dr. Martha Yearsley.

Fig. 24 This colon biopsy from a patient who had lived in Vietnam shows extensive mucosal destruction with acute, chronic, and loosely granulomatous inflammation (A). At high power, macrophages packed with small organisms can be seen (B, arrows).

Fig. 25 *T. marneffei* are small, ovoid, and do not bud (A, GMS stain). Instead, they divide by forming transverse septations (arrows, GMS).

Clinical features

Patients with gastrointestinal involvement typically present with fever and diarrhea. Most, but not all, cases of gastrointestinal pneumocystis also have pulmonary involvement (Dieterich et al., 1992; Bellomo et al., 1992).

Gross findings

Macroscopically, *P. jirovecii* infection produces a nonspecific, often erosive, esophagogastritis or enterocolitis, occasionally with small polypoid nodules. Any portion of the gastrointestinal tract may be involved, including mesenteric lymph nodes (Dieterich et al., 1992).

Microscopic findings

As in the lung, a wide variety of inflammatory responses may occur in the gastrointestinal tract, including prominent macrophage infiltrates, necrosis, and occasionally granulomas (Cooper and McGinnis, 1997). The classic granular, foamy eosinophilic casts seen in pulmonary *Pneumocystis* infection can also be found in the GI tract, either in mucosal vessels or in the lamina propria and submucosa (Fig. 26). Because granulomatous reactions are rare with *Pneumocystis*, concurrent pathogens should be excluded when granulomas are seen. The organisms are 4–6 μm spherules, typically extracellular, that have cup or crescent shapes when collapsed (Fig. 27). Many contain characteristic paired comma-shaped internal structures.

Differential diagnosis

P. jirovecii can usually be correctly classified in tissue sections based on features and the characteristic foamy casts. As noted above, the major organisms in the differential diagnosis are *H. capsulatum*, *Cryptococcus* spp., and *T. marneffei*. *P. jirovecii* does not bud, unlike *H. capsulatum* and *Cryptococcus* spp., and is generally larger and lacks the transverse septum of *T. marneffei*. The beta (1.3) D glucan assay is also helpful in this situation, as it is positive in *P. jirovecii* infection but the morphologic features are significantly different from those of the filamentous fungi.

Microsporidiosis

Microsporidiosis is an infection caused by multiple species of a highly specialized fungus that for years was believed to be a parasite (coccidian) (Han and Weiss, 2017). Microsporidia have a worldwide distribution, and are present in many environmental sources. They have many animal hosts as well. Many are capable of infecting multiple organ systems, but *Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*, and *Encephalitozoon hellem* are most commonly seen in the GI tract. This infection is particularly important when considering the differential diagnosis of diarrhea in patients with AIDS (Curry and Smith, 1998; Franzen et al., 1999;

Fig. 26 This case of *Pneumocystis jirovecii* enteritis shows the characteristic foamy casts filling the submucosa.

Goodgame, 1996). Transmission is normally via the fecal-oral route, either directly or through contaminated food and water. These fungi are also a cause of self-limited traveler's diarrhea. Albendazole is the mainstay of treatment, although *E. bienensei* and some other species are resistant to this drug, posing a significant challenge for profoundly immunocompromised individuals with persistent disease. In some cases, immune restoration is the only treatment option.

Clinical features

Chronic nonbloody, nonmucoid diarrhea is the most common presentation, variably accompanied by fever, weight loss, abdominal pain, and malaise. Stool does not usually contain red blood cells or leukocytes (Curry and Smith, 1998; Franzen et al., 1999; Goodgame, 1996; Field and Milner Jr., 2015; Orenstein et al., 1994). In immunocompetent persons, infection is usually self-limited, but immunocompromised patients are at risk for chronic, severe diarrhea, with malabsorption, dehydration, and eventual death. Disseminated infection may occur, especially with *E. intestinalis* infection. Endoscopic findings are usually absent or mild.

Gross findings

Any level of the gastrointestinal tract may be affected, including the biliary tree, but the small bowel is the most common site of infection.

Microscopic findings

Microsporidia are notoriously difficult to detect in routine H&E stained sections due to their incredibly small size (Field and Milner, 2015). Characteristic findings include mild villous blunting, a patchy lamina propria lymphoplasmacytic infiltrate, variably

Fig. 27 *Pneumocystis jirovecii* organisms are extracellular and are seen on GMS as spheres with a cup or crescent shapes when collapsed. Occasional dot or comma-like internal structures can be seen (A, GMS). Fig. (B) shows a calcofluor white fungal smear, which clearly shows the internal comma-like structures (arrows).

increased surface intraepithelial lymphocytes, vacuolization of the surface epithelium, and surface epithelial cell disarray (Fig. 28). There may be minimal to no tissue reaction, however.

The organisms are present as small spores within host cells. While the size of the microsporidia that infect humans ranges from 0.7 to 4 μm , the spores of *E. bienersi* and the *Encephalitozoon* species are only 0.7–1.4 μm in greatest dimension. In intestinal microsporidiosis, the spores are located within the supranuclear cytoplasm of epithelial cells or occasionally lamina propria macrophages (most common with *E. intestinalis*). Associated vacuoles may cup or flatten the enterocyte nucleus.

A modified trichrome stain can aid greatly in the diagnosis (Fig. 29), and the organisms also stain with Warthin-Starry, Giemsa, Gram, Ziehl-Neelsen, and GMS stains, although staining with the latter two is often focal (Field and Milner, 2015; Lamps et al., 1998). PAS stain may show a positive granule at one end of each spore. Occasionally, microsporidial spores polarize within biopsy specimens, since the chitin-rich internal polar filament of the organism is birefringent under polarized light. However, this method is unreliable, due to unpredictability of spore birefringence, and variability depending on the type of microscope and light source used (Lamps et al., 1998).

Fig. 28 This small bowel biopsy with microsporidia yeasts shows a subtle supranuclear vacuolization (arrows) with surface epithelial cell disarray and scattered intraepithelial lymphocytes.

Fig. 29 A modified trichrome stain highlights the spores in microsporidial spores infection.

Differential diagnosis

The differential diagnosis includes other small yeasts, as well as *Leishmania* spp., intracellular bacteria, and phagocytosed material. Although often difficult to appreciate on H&E stain, the microsporidia are the only fungi in the differential diagnosis that are typically present within surface epithelial cells. *Leishmania* spp. are typically present within macrophages in the GI tract, and are Giemsa positive, GMS negative, and have a kinetoplast. *Histoplasma capsulatum* yeasts are also present within macrophages, produce buds, and are uniformly GMS positive; they have a "halo" around the organism on H&E stain. Similarly, *C. glabrata* has buds and is uniformly GMS positive, and is typically not present within surface epithelial cells. *T. marneffe* has a transverse septum, and is usually also present within macrophages. Transmission electron microscopy is still considered the gold standard for confirming diagnosis, although it is being replaced with sequence analysis. The availability of both is severely limited. There are commercially available immunofluorescence assays available for some species, and PCR is available at some laboratories. Stool O&P studies may be helpful if special stains (chromotrope 2R modified trichrome) are used, but diagnosis may be challenging due to the resemblance to small yeasts or bacteria.

Introduction	138
Parasite taxonomy	139
Diagnosis of gastrointestinal parasites	139
Parasites of the oral cavity	139
Entamoeba gingivalis	142
Trichomonas tenax	144
Leishmania spp. (mucocutaneous leishmaniasis)	145
Biology and epidemiology	145
Pathogenesis, clinical presentation, and treatment	145
Diagnosis	145
Nematode infections	146
Gongylonema pulchrum (gongylonemiasis)	146
Anatrichosoma spp. (anatrichosomiasis)	146
Arthropod infections	147
Oral myiasis	147
Parasites of the esophagus and stomach	148
Protozoan infections	148
Trypanosoma cruzi (chagasic achalasia/chagasic megaesophagus)	148
Nematode infections	149
Anisakis spp., Pseudoterranova spp., and Contracaecum spp. (anisakiasis)	149
Parasites of the small intestine	150
Protozoan infections	150
Giardia duodenalis (giardiasis)	150
Cryptosporidium spp. (cryptosporidiosis)	152
Cyclospora cayetanensis (cyclosporiasis)	154
Cystoisospora belli (cystoisosporiasis)	155
Sarcocystis hominis, S. suis hominis (intestinal sarcocystosis)	156
Nematode infections	156
Ascaris lumbricoides (ascariasis)	156
Capillaria philippinensis (intestinal capillariasis)	158
Necator americanus and Ancylostoma species (intestinal hookworm infection)	159
Trichostrongylus species (trichostrongylosis)	161
Strongyloides stercoralis (strongyloidiasis)	161
Trichinella species (trichinellosis, trichinosis)	164
Angiostrongylus costaricensis (human abdominal angiostrongyliasis)	166
Trematode infections	166
Fasciolopsis buski (fasciolopsiasis)	166
Heterophyes heterophyes, Metagonimus yokogawai, and other small intestinal trematodes (heterophyiasis, metagonimiasis)	168
Miscellaneous intestinal trematodes	168
Nanophyetus salmincola (nanophyetiasis)	168
Echinostoma spp. and related (echinostomiasis)	168
Neodiplostomum seoulense (Neodiplostomum infection)	169
Cestode infections	169
Dibothriocephalus spp., Diphylobothrium spp., and Adenocephalus spp. (diphylobothriasis, fish tapeworm disease)	169
Taenia saginata, Taenia solium, Taenia suis hominis (intestinal taeniasis)	170
Hymenolepis nana, Hymenolepis diminuta (hymenolepiasis)	172
Dipylidium caninum (dipylidiasis, dog tapeworm disease)	173
Miscellaneous cestode infections	174
Raillietina spp. (raillietiniasis)	174
Inermicapsifer madagascariensis (Inermicapsifer infection)	175
Bertiella species (bertiellosis)	175
Mesocystoides spp. (mesocystoidiasis)	175
Acanthocephalan infections	176

<i>Macracanthorhynchus</i> species, <i>Moniliformis moniliformis</i> (acanthocephaliasis)	176
Parasites of the appendix and large intestine, and anus	177
Protozoan infections	177
<i>Entamoeba histolytica</i> (intestinal amebiasis)	177
<i>Dientamoeba fragilis</i> (<i>Dientamoeba</i> infection)	179
<i>Balantiodides coli</i> (balantiosis)	180
<i>Blastocystis</i> spp. (blastocystosis)	180
Non-pathogenic intestinal protozoa	182
<i>Entamoeba hartmanni</i>	182
<i>Entamoeba coli</i>	182
<i>Entamoeba polecki</i> and <i>E. chattoni</i>	182
<i>Endolimax nana</i> and <i>Iodamoeba buetschlii</i>	183
<i>Chilomastix mesnili</i>	183
<i>Pentatrichomonas hominis</i>	183
<i>Enteromonas hominis</i> and <i>Retortamonas intestinalis</i>	183
Nematode infections	183
<i>Enterobius vermicularis</i> (enterobiasis, pinworm infection)	183
<i>Trichuris trichiura</i> (trichuriasis, whipworm infection)	185
<i>Oesophagostomum</i> spp. (oesophagostomiasis)	185
Trematode infections	185
<i>Schistosoma</i> species (intestinal schistosomiasis, bilharzia)	185
<i>Gastrodiscoides hominis</i> (<i>Gastrodiscoides</i> infection)	187
Parasites of the liver and biliary tree	187
Protozoan infections	187
<i>Entamoeba histolytica</i> (hepatic amebiasis)	187
<i>Leishmania</i> species (visceral leishmaniasis, kala-azar)	188
Nematode infections	189
<i>Capillaria hepatica</i> (hepatic capillariasis)	189
<i>Toxocara canis</i> , <i>T. cati</i> (visceral larval migrans, toxocariasis)	190
Trematode infections	191
<i>Schistosoma</i> species (hepatosplenic schistosomiasis)	191
<i>Fasciola hepatica</i> and <i>F. gigantica</i> (fascioliasis)	192
<i>Clonorchis sinensis</i> , <i>Opisthorchis viverrini</i> , <i>O. felinus</i> (clonorchiasis, opisthorchiasis)	194
<i>Dicrocoelium dendriticum</i> , <i>D. hospes</i> (dicrocoeliasis)	195
Cestode infections	195
<i>Echinococcus granulosus</i> -complex (cystic echinococcosis)	195
<i>Echinococcus multilocularis</i> (alveolar echinococcosis)	196

Glossary

Commensal A parasite that benefits from its host but does not damage its host.

Cyst The environmentally hardy stage in the protozoan life cycle responsible for transmission.

Definitive host A host in which sexual maturity and reproduction of the parasite takes place.

Dead-end host A host in which a parasite cannot develop to adulthood; the term is usually applied a host that is not part of the natural life cycle.

Embryonation The process of in the development of a helminth egg that results in the formation of a larva that is infectious to the next host. Eggs may be shed in the feces of the definitive host unembryonated (no differentiation of the developing larva), partially embryonated, or fully embryonated (containing an infectious larva).

Intermediate host A host in which larval development or asexual reproduction takes place.

Oocyst The environmentally hardy state in the life cycle of apicomplexan parasites; in *Cryptosporidium* and the coccidians, it is the stage responsible for transmission.

Operculum A small lid-like opening on the eggs of trematodes (exclusive of *Schistosoma* spp.) and diphyllbothriid cestodes.

Paratenic host A host in which harbors the larva or immature stage of a parasite, but further development of the parasite does not take place.

Trophozoite The stage of a protozoan responsible for feeding and replication by binary fission.

Vector An arthropod or other animal that mechanically transfers a pathogen to a host, usually while feeding.

Zoonotic Refers to a parasite that does not routinely infect humans as part of its natural life cycle.

Introduction

Gastrointestinal (GI) parasites encompass a broad array of parasites, including protozoa, helminths, and rarely, arthropods. Each of these groups of parasites can be divided into further categories: the protozoa by their type of motility (e.g., flagellates, ciliates, amebae), and the helminths by their overall morphology (roundworms, flatworms, and the acanthocephalans). Some of these parasites are commensal organisms (i.e., parasite that do not damage their host), whereas others are potential pathogens. This chapter will cover important parasites that involve all regions of the GI tract, from mouth to anus, including the liver and biliary tree (See Tables 1–5).

Parasites were the earliest type of GI pathogens reported in human writings, owing to the ability of some to be seen with the unaided eye and their association with clearly-defined clinical syndromes (Cox, 2002). The Egyptian Ebers papyrus (circa 3000 to 400 BCE) described parasitic infections which are now clearly recognized as ascariasis, echinococcosis, enterobiasis, and schistosomiasis. Descriptions of these infections later appeared in writings by physicians in Greece, China, India, Rome and the Arab Empire. Today, parasites remain an important cause of human morbidity and mortality and have a significant economic impact in many parts of the developing world. Several GI parasitic diseases are categorized by the World Health Organization (WHO) as Neglected Parasitic Diseases (NTDs) due to the devastating effect they have on individuals living in poverty (WHO, 2020a). These diseases are estimated to affect more than one billion people worldwide, and result in substantial losses in productivity, income, and human lives. Among the 20 NTDs, seven categories involve the GI tract: foodborne trematodiasis, soil-transmitted helminthiasis, schistosomiasis, Chagas disease, echinococcosis, leishmaniasis, and taeniasis/cysticercosis. Chagas disease is also recognized by the United States Centers for Disease Control and Prevention (CDC) as a Neglected Parasitic Infection (NPI), targeted as a priority for public health action (CDC, 2020b). This group of five parasitic infections has been selected based on the number of individuals impacted in the United States, the severity of the associated illnesses, and the ability to prevent and treat infections. Cysticercosis is another relevant NPI that will be considered in this chapter as it is linked to the GI infection, taeniasis, caused by infection with the cestode *Taenia solium*. In addition to the NTDs and NPIs, there are a large number of parasitic infections that are recognized by the WHO, CDC, and other public health organizations as important causes of diarrheal illnesses. In 2010, the WHO estimated that infections with the enteric protozoan parasites, *Entamoeba histolytica*, *Giardia duodenalis*, and *Cryptosporidium*, were responsible for more than 3.5 million illnesses, and 60,000 deaths worldwide (Kirk et al., 2015).

Infections with potentially-pathogenic GI parasites are often asymptomatic, particularly at low levels of infection. However, infections may be associated with a range of symptoms due to the mechanical or chemical damage caused by the parasite and the associated host immune response. While some parasites cause only localized disease, others may cause extraintestinal

Table 1 Parasites of the oral cavity.

Disease [agent(s)]	Clinical Manifestations	Diagnosis [secondary, alternative methods]
Protozoan Infections		
<i>Entamoeba gingivalis</i>	None; often associated with periodontitis	Microscopy
<i>Trichomonas tenax</i>	None; often associated with periodontitis, rarely pleural empyema	Microscopy
Mucocutaneous Leishmaniasis [<i>Leishmania braziliensis</i> , <i>L. panamensis</i> , <i>L. amazonensis</i> , <i>L. guyanensis</i>]	Initially epistaxis, rhinorrhea, nasal stuffiness, lymphadenopathy; progresses to chronic expanding ulceration of the lips, nostril or palate. Previous scar from healed cutaneous disease commonly present.	Microscopy, culture, nucleic acid amplification tests
Chagas Disease Sialorrhea [<i>Trypanosoma cruzi</i>]	Drooling	Antibody detection; microscopy is rarely useful (amastigotes not usually seen)
Nematode Infections		
Gongylosomiasis [<i>Gongylonema pulchrum</i>]	Oral sensations, nausea, vomiting	Microscopy (gross examination of adult worms; histopathology)
Anatrichosomiasis [<i>Anatrichosoma</i> spp.]	Painful blisters on the oral mucosa, lips, tongue, hard and soft palate	Microscopy (histopathology)
Trichinellosis (trichinosis) [<i>Trichinella</i> spp.] ^a	Diarrhea, abdominal pain, vomiting, eosinophilia, myalgia, muscle weakness, facial edema, hoarse voice	Antibody detection [histopathology]
Arthropod Infections		
Oral Myiasis [<i>Cochliomyia hominivorax</i> , <i>Wohlfahrtia magnifica</i> , <i>Musca domestica</i> , <i>Calliphora vicina</i> , <i>Chrysomya bezziana</i> , <i>Oestrus ovis</i> , <i>Hypoderma bovis</i> , <i>H. tarandi</i> , <i>Gasterophilus intestinalis</i>]	Pain, swelling, live maggots observed in oral mucosa	Gross morphology of extracted fly larvae

^aTrichinellosis will be covered in this chapter under Parasites of the Small Intestine.

Table 2 Parasites of the esophagus and stomach.

Disease [agent(s)]	Clinical Manifestations	Diagnosis [secondary, alternative methods]
Protozoan Diseases Chagasic Achalasia/Chagasic Megaesophagus [<i>Trypanosoma cruzi</i>]	Dysphasia, regurgitation, weight loss, malnutrition	Antibody detection; microscopy is rarely useful (amastigotes not usually seen)
Nematode Infections Anisakiasis [<i>Anisakis</i> spp., <i>Pseudoterranova</i> spp., <i>Contracaecum</i> spp.]	Acute onset of severe epigastric pain; live larva may be retrieved from the mouth, esophagus or stomach; allergic symptoms	Microscopy (gross morphologic identification of intact worms expelled live or extracted by endoscopy; histopathology) [Antibody detection]

manifestations during the usual course of their life cycle or as a result of ectopic spread within their host. Examples of extraintestinal manifestation include a pruritic cutaneous lesion at the site of initial host skin penetration (hookworm and *Strongyloides stercoralis*), bacterial sepsis (*S. stercoralis*, *Trichuris trichiura*), and abscess-like lesions in various organs (*Entamoeba histolytica*).

Parasite taxonomy

Parasite taxonomy has evolved substantially over the past few decades. Parasites were traditionally placed into two Kingdoms: the Protozoa (single-celled eukaryotic organisms) and Animalia (helminths and arthropods). Parasites were further categorized into phylum, class, order and family groupings based on physiologic, ecologic and subjective morphologic criteria. While this hierarchical system is still used in some settings, parasitologists have increasingly recognized the inability of the traditional system to reflect true phylogenetic parasite relatedness. In contrast, modern classification schemes incorporate molecular analyses such as whole genome sequencing to place parasites into clades based upon genetic relatedness (Adl and Mathison, 2019; Adl et al., 2019). In the widely-recognized system by the International Society of Protistologists, human parasites are placed within five *supergroups*: the Amoebozoa, Archaeplastida, Excavata, SAR, and Opisthokonta. Many familiar groupings have been retained in this schema to facilitate correlation with the traditional taxonomic system. At this time, the modern classification system is used primarily for the protozoan parasites. It remains common for helminth and arthropod parasites to be described using the traditional taxonomy scheme.

Diagnosis of gastrointestinal parasites

A variety of methods are used in the diagnosis of gastrointestinal parasitic infections. Traditional morphologic examination of gross and microscopic preparations remains the gold standard method for detection and identification many parasites, including the intestinal helminths and commensal protozoa. Light microscopic examination of unstained and stained preparations can also be used for detection of common intestinal protozoa, although stool immunoassays and/or nucleic acid amplification tests (NAATs) generally offer greater sensitivity and specificity, and there are commercial options available for common pathogenic parasites (Garcia et al., 2018). Antibody detection has the greatest utility for detecting evidence of parasites that are not readily seen within easily-acquired specimens such as stool and sputum. Situations in which serology is particularly useful are for supporting the clinicoradiologic diagnosis of amebic liver abscess and hepatic echinococcosis, and diagnosing schistosomiasis in the absence of identifiable eggs in the stool. Finally, culture methods are used for identification and study of select parasites in research settings. These methods are not commonly used for routine diagnosis in the clinical laboratory, and are generally limited to the specialty reference/public health laboratory or research setting. In the United States, several parasite culture methods are performed at the CDC's Division of Parasitic Diseases and Malaria. For specific procedures, recipes, and guidance on Quality Assurance, the reader is directed to the CDC's DPDx website (<https://www.cdc.gov/dpdx/diagnosticprocedures/index.html>) as well as several excellent references (Ash and Orihel, 1987, 2007; Carroll et al., 2019; Couturier et al., 2015; Garcia, 2016; Garcia et al., 2018). All specimens must be handled with great care since they may pose an infection risk to humans.

Diagnostic methods for specific parasites will be discussed in detail below under the specific diseases they cause.

Parasites of the oral cavity

A small number of parasites can involve the oral cavity (Table 1). While some like *Trichomonas tenax* are considered commensal organisms, not thought to cause disease, others such as *Leishmania* can cause destructive and potentially life-threatening damage.

Table 3 Parasites of the small intestine.

Disease [agent (s)]	Clinical Manifestations	Diagnosis [secondary, alternative methods]
Protozoan Diseases		
Giardiasis [<i>Giardia duodenalis</i>]	Commonly asymptomatic; explosive foul-smelling watery/fatty/mucous diarrhea, belching, flatulence	Microscopy (O&P examination), antigen detection, NAATs
Cryptosporidiosis [<i>Cryptosporidium</i> spp.]	May be asymptomatic; profuse watery, prolonged diarrhea, nausea/vomiting, abdominal pain, low-grade fever. Worse in immunocompromised individuals.	Microscopy (modified acid-fast, safranin stains), antigen detection, NAATs
Cyclosporiasis [<i>Cyclospora cayetanensis</i>]	May be asymptomatic; profuse watery, prolonged diarrhea, nausea/vomiting, abdominal pain, low-grade fever. Worse in immunocompromised individuals.	Microscopy (modified acid-fast, safranin stains; UV autofluorescence), NAATs
Cystoisosporiasis [<i>Cystoisospora belli</i>]	May be asymptomatic; profuse watery, prolonged diarrhea, nausea/vomiting, abdominal pain, low-grade fever. Worse in immunocompromised individuals. Occasionally peripheral eosinophilia.	Microscopy (O&P examination, modified acid-fast, safranin, UV autofluorescence, histopathology)
Intestinal Sarcocystosis [<i>Sarcocystis hominis</i> , <i>S. suis</i>]	May be asymptomatic; profuse watery, prolonged diarrhea, nausea/vomiting, abdominal pain, low-grade fever. Worse in immunocompromised individuals. Occasionally peripheral eosinophilia.	Microscopy (O&P examination, modified acid-fast, UV autofluorescence)
Chagas Disease [<i>Trypanosoma cruzi</i>]	Chronic diarrhea	Antibody detection; microscopy is rarely useful (amastigotes not usually seen)
Nematode Infections		
Ascariasis [<i>Ascaris lumbricoides</i>]	May be asymptomatic; manifestations are often proportional to the worm burden: Loeffler's syndrome, abdominal discomfort, anorexia, diarrhea, small bowel obstruction, ectopic migration with appendicitis, pancreatitis	Microscopy (wet mounts of stool, gross morphology of adults, histopathology)
Intestinal Capillariasis [<i>Capillaria philippinensis</i>]	Abdominal pain, chronic watery diarrhea, vomiting, anorexia, weight loss, malabsorption; may be fatal overtime due to ongoing autoinfection.	Microscopy (wet mounts of stool, histopathology)
Intestinal Hookworm Infection [<i>Necator americanus</i> , <i>Ancylostoma duodenale</i> , <i>A. ceylanicum</i>]	May be asymptomatic; manifestations are often proportional to the worm burden: rash at initial skin penetration, Loeffler's syndrome, abdominal pain, diarrhea, anemia (may be severe), hypoalbuminemia, malnutrition	Microscopy (wet mounts of stool, gross morphology of adults)
Trichostrongyliasis [<i>Trichostrongylus</i> spp.]	Usually asymptomatic; nausea, anorexia, diarrhea, pulmonary symptoms, eosinophilia	Microscopy (wet mounts of stool, Kato-Katz)
Strongyloidiasis [<i>Strongyloides stercoralis</i> , <i>S. fuelborni</i>]	Commonly asymptomatic; rash at initial skin penetration, Loeffler's syndrome, hyperinfection in immunocompromised patients may cause bloody diarrhea, recurrent bacterial sepsis and meningitis, pulmonary hemorrhage, respiratory collapse, death	Microscopy (wet mounts of stool, Kato-Katz, Baermann technique, string test, histopathology), Culture, Antibody Detection
Trichinellosis (trichinosis) [<i>Trichinella</i> spp.]	Intestinal and muscular/systemic phases; intestinal phase with self-limited diarrhea and abdominal pain. Muscular/systemic phase with peripheral eosinophilia, facial edema, vasculitis, intravascular thrombosis, conjunctivitis, muscle pain, elevated muscle enzymes.	Antibody Detection [Microscopy (pepsin-digestion, histopathology), NAATs]
Human Abdominal Angiostrongyliasis [<i>Angiostrongylus costaricensis</i>]	Eosinophilic enteritis, fever, anorexia, vomiting, and RUQ pain	Morphology (histopathology)
Anisakiasis [<i>Anisakis</i> spp., <i>Pseudoterranova</i> spp., <i>Contracaecum</i> spp.]	Abdominal pain	Microscopy (gross morphologic identification of intact worms expelled live or extracted by endoscopy; histopathology) [immunodiagnosis]
Trematode Infections		
Fasciolopsiasis [<i>Fasciolopsis buski</i>]	May be asymptomatic; manifestations are often proportional to the worm burden: epigastric pain, nausea, diarrhea, malabsorption, protein-losing enteropathy, peripheral eosinophilia, anemia.	Microscopy (wet mounts of stool, gross morphology of adult)
Heterophyiasis, Metagonimiasis [<i>Heterophyes heterophyes</i> , <i>Metagonimus yokogawai</i> , many others]	May be asymptomatic; manifestations are often proportional to the worm burden: abdominal pain, diarrhea, peripheral eosinophilia	Microscopy (wet mounts of stool)
Nanophyetiasis [<i>Nanophyetis salmincola</i>]	Abdominal pain, nausea, vomiting, weight-loss, increased number of bowel movements, fatigue, eosinophilia	Microscopy (wet mounts of stool)
Echinostomiasis [<i>Echinostoma</i> spp., several others]	epigastric and abdominal pain, malaise, weight loss, anorexia, nausea, vomiting, and diarrhea	Microscopy (wet mounts of stool)

<i>Neodiplostomum</i> infection [<i>Neodiplostomum seoulense</i>]	Abdominal pain, fever	Microscopy (wet mounts of stool)
Intestinal Schistosomiasis ^a [<i>Schistosoma japonicum</i> , <i>S. mekongi</i>]	Abdominal pain, anorexia, bloody diarrhea	Microscopy (wet mounts of stool; histopathology); Antibody Detection
Cestode Infections		
Diphyllobothriasis (fish tapeworm disease) [<i>Dibothriocephalus</i> spp., <i>Diphyllobothrium</i> spp., <i>Adenocephalus</i> spp.]	Commonly asymptomatic; abdominal pain, diarrhea, constipation, fatigue, vitamin B ₁₂ deficiency, passing chains of proglottids.	Microscopy (wet mounts of stool, gross morphology of adults)
Intestinal Taeniasis [<i>Taenia saginata</i> , <i>T. solium</i> , <i>T. sui hominis</i>]	Commonly asymptomatic; abdominal pain, diarrhea, constipation, fatigue, passing individual or chains of proglottids.	Microscopy (wet mounts of stool, gross morphology of adults) [coproantigen testing]
Hymenolepiasis [<i>Hymenolepis nana</i> , <i>H. diminuta</i>]	Commonly asymptomatic; poor growth and development in children	Microscopy (wet mounts of stool, gross morphology of adults)
Dipylidiasis (dog tapeworm disease) [<i>Dipylidium caninum</i>]	Commonly asymptomatic; diarrhea, restlessness, abdominal discomfort, anal pain and itching	Microscopy (gross morphology of adults, wet mounts of stool)
Miscellaneous Cestode Infections [<i>Raillietina</i> spp., <i>Inermicapsifer</i> <i>madagascariensis</i> , <i>Bertiella stuederi</i> , <i>B. mucronotata</i> , <i>Mesocestoides</i> spp.]	Commonly symptomatic; generalized gastrointestinal symptoms	Microscopy (gross morphology of adults, eggs liberated from proglottids)
Acanthocephalan Infections		
Acanthocephaliasis [<i>Macracanthorhynchus hirudinaceus</i> , <i>M. ingens</i> , <i>Moniliformis moniliformis</i>]	May be asymptomatic, abdominal pain, rarely intestinal perforation.	Microscopy (gross morphology of adults and eggs liberated therefrom)

Abbreviations: NAAT – nucleic acid amplification test.

^aIn this chapter, intestinal schistosomiasis is covered under Parasites of the Appendix, Large Intestine, and Anus.

Table 4 Parasites of the appendix, large intestine, and anus.

Disease [agent(s)]	Clinical Manifestations	Diagnosis [secondary, alternative methods]
Protozoan Infections		
Amebiasis [<i>Entamoeba histolytica</i>]	Commonly asymptomatic; watery to bloody diarrhea, dysentery, fulminant necrotizing colitis, ameboma, disseminated disease (e.g., liver involvement), death	Microscopy (O&P examinations of stool, histopathology), antigen detection, antibody detection, NAATs
<i>Dientamoeba fragilis</i> Infection [<i>Dientamoeba fragilis</i>]	Pathogenesis is controversial; associated with abdominal pain, diarrhea, constipation, peripheral eosinophilia	Microscopy (O&P examinations of stool), NAATs
Balantidiasis [<i>Balantidium coli</i>]	May be asymptomatic; abdominal pain, watery to bloody diarrhea, dysentery, fulminant necrotizing colitis, disseminated disease, death	Microscopy (O&P examinations of stool, histopathology)
Blastocystosis [<i>Blastocystis</i> spp.]	Pathogenesis is controversial; associated with abdominal pain, diarrhea, increased flatulence, anorexia	Microscopy (O&P examinations of stool), NAATs
Miscellaneous nonpathogenic protozoa [<i>Entamoeba hartmanni</i> , <i>E. coli</i> , <i>E. polecki</i> , <i>E. chattoni</i> , <i>Endolimax nana</i> , <i>Iodamoeba buetschlii</i> , <i>Chilomastix mesnili</i> , <i>Pentatrichomonas hominis</i> , <i>Enteromonas hominis</i> , <i>Retortamonas intestinalis</i>]	None; organisms are nonpathogenic	Microscopy (O&P examinations of stool)
Chagasic Megacolon [<i>Trypanosoma cruzi</i>]	Chronic constipation	Antibody detection; microscopy is rarely useful (amastigotes not usually seen)
Nematode Infections		
Enterobiasis (Pinworm Infection) [<i>Enterobius vermicularis</i>]	May be asymptomatic; nocturnal pruritus ani, insomnia, ectopic disease (e.g. appendicitis, vulvovaginitis)	Microscopy (Observation of eggs on cellulose tape preps; gross morphology of adult worms; histopathology) [wet mounts of stool]
Trichuriasis (Whipworm Infection) [<i>Trichuris trichiura</i>]	May be asymptomatic; manifestations are often proportional to the worm burden: abdominal pain, diarrhea, anemia (may be severe), malnutrition, rectal prolapse	Microscopy (wet mounts of stool; gross morphology of adult worms; histopathology)
Oesophagostomiasis [<i>Oesophagostomum</i> spp.]	Acute abdomen, low-grade fever, anorexia, vomiting, diarrhea, purulent peritonitis	Microscopy (wet mounts of stool)
Trematode Infections		
Intestinal Schistosomiasis [<i>Schistosoma mansoni</i> , <i>S. intercalatum</i> , <i>S. guineensis</i> , <i>S. japonicum</i> , <i>S. mekongi</i>]	May be asymptomatic in early disease; cercarial dermatitis, Katayama fever, abdominal pain, anorexia, blood diarrhea.	Microscopy (wet mounts of stool; histopathology), Antibody Detection
<i>Gastrodiscoides</i> Infection [<i>Gastrodiscoides hominis</i>]	Diarrhea with mucus	Microscopy (wet mounts of stool; gross morphology of adults)

Entamoeba gingivalis

Entamoeba gingivalis is generally considered a commensal in the human oral cavity. While it has been associated with certain clinical conditions, such as periodontitis (Bonner et al., 2018) and osteomyelitis of the mandible (Bhaijee and Bell, 2011), its presence under such circumstances is not entirely understood, and it is generally considered incidental and the amebae are probably feeding on bacteria associated with these conditions (Dubar et al., 2020). HIV-positive patients may show a higher prevalence of *E. gingivalis* due to the accelerated development of chronic periodontitis in these patients (Cembranelli et al., 2013), but its role as a pathogen is still unclear. Ectopic colonization of the female urogenital tract has been associated with contaminated intrauterine devices (IUDs) (Bradbury et al., 2019).

Diagnosis of *E. gingivalis* infection is made by microscopic examination of tooth and gum scrapings stained with routine microbiologic stains (e.g. Wheatley's trichrome stain), or rarely, tissue biopsies stained with hematoxylin and eosin (H&E), periodic acid-Schiff (PAS) and Masson's trichrome (Bhaijee and Bell, 2011). *Entamoeba gingivalis* exists only in the trophozoite stage; unlike the other human-infecting *Entamoeba* spp., there is no cyst stage (Vráblík et al., 1991). The trophozoites have the classic morphologic features of all amebic trophozoites, including a round-to-oval-to irregular shape with pseudopod projections. There is a single nucleus with the features of typical "Entamoeba-type" nuclei including a relatively-small karyosome and peripheral chromatin (Fig. 1). Subtle variations of this appearance are used to differentiate the various *Entamoeba* spp.: the trophozoites of *E. gingivalis* are 8.0-20.0 µm in greatest dimension and have a nucleus with a centrally-located karyosome and equally-distributed peripheral chromatin. The cytoplasm is finely granular and may contain ingested erythrocytes, leukocytes, epithelial cells, and bacteria.

Table 5 Parasites of the liver and biliary tree.

<i>Disease [agent(s)]</i>	<i>Clinical Manifestations</i>	<i>Diagnosis [secondary, alternative methods]</i>
Protozoan Infections		
Hepatic Amebiasis [<i>Entamoeba histolytica</i>]	Right upper quadrant pain, fever, complications: rupture into peritoneal cavity, obstructive jaundice, bacterial superinfection.	Imaging, Antibody Detection, NAATs [Microscopy (permanent stained smears; histopathology)]
Visceral Leishmaniasis (kala-azar) [<i>Leishmania donovani</i> , <i>L. infantum</i>]	May be asymptomatic in latent stage; active disease fatal if untreated: persistent fever, hepatosplenomegaly, pancytopenia, weight loss, wasting, skin hyperpigmentation	Antibody Detection [Microscopy (Giemsa-stained smears; histopathology); NAATs; culture]
Nematode Infections		
Hepatic Capillariasis [<i>Capillaria hepatica</i>]	Persistent fever, peripheral eosinophilia, abdominal pain, elevated hepatic enzymes, watery diarrhea, asthma-like symptoms	Microscopy (histopathology)
Visceral Larval Migrants (toxocariasis, baylisascariasis) [<i>Toxocara canis</i> , <i>T. cati</i> , <i>Baylisascaris procyonis</i>]	May be asymptomatic; fever, hepatosplenomegaly, asthma-like symptoms, high peripheral eosinophilia	Antibody Detection [Microscopy (histopathology)]
Trematode Infections		
Hepatic Schistosomiasis ^a [<i>Schistosoma mansoni</i> , <i>S. japonicum</i> , <i>S. mekongi</i>]	Portal hypertension, leading to ascites, esophageal varices, severe anemia, delayed growth in children.	Microscopy (histopathology), Antibody Detection
Fascioliasis [<i>Fasciola hepatica</i> , <i>F. gigantica</i>]	Commonly asymptomatic; fever, myalgia, arthralgia, peripheral eosinophilia, abdominal pain, cholelithiasis, cholangitis, pancreatitis, biliary cirrhosis	Microscopy (detection of eggs in wet mounts of stool), Antibody Detection [histopathology, gross morphology of adults]
Opisthorchiasis, Clonorchiasis, Metorchiasis [<i>Opisthorchis viverrini</i> , <i>O. felinus</i> , <i>Clonorchis sinensis</i> , <i>Metorchis conjunctus</i>]	Commonly asymptomatic; cholangitis, cholelithiasis, hepatomegaly, obstructive jaundice, cholangiocarcinoma.	Microscopy (detection of eggs in wet mounts of stool) [antibody detection, NAATs]
Dicrocoeliasis [<i>Dicrocoelium dendriticum</i> , <i>D. hospes</i>]	Peripheral eosinophilia, abdominal distention, RUQ pain, diarrhea, constipation, anemia, and weight loss, cholecystitis, liver abscesses	Microscopy (detection of eggs in wet mounts of stool)
Cestode Infections		
Cystic Echinococcosis [<i>Echinococcus granulosus</i> , <i>E. canadensis</i> , <i>E. equinus</i> , <i>E. ortleppi</i> , <i>E. oligarthra</i> , <i>E. vogeli</i>]	May be asymptomatic for many years; abdominal discomfort, decreased appetite, enlarging abdominal mass over many years; cyst leakage can cause life-threatening allergic reactions	Imaging Analysis, Antibody Detection [Microscopy (histopathology; wet mount examination of aspirates)]
Alveolar Echinococcosis [<i>Echinococcus multilocularis</i>]	Fatal if not treated; abdominal pain and damage to neighboring organs due to infiltrating cysts.	Imaging Analysis, Antibody Detection, Microscopy (histopathology)

^aIn this chapter, schistosomiasis is covered in detail under Parasites of the Appendix, Large Intestine, and Anus.

Species	<i>Entamoeba polecki</i>	<i>Entamoeba histolytica/E. dispar</i>	<i>Entamoeba coli</i>	
Cyst				
Trophozoite				

Scale 20 μ m

Fig. 1 Common intestinal amebae (Wheatley's Trichrome stain, 1000 $\times$ original magnification). The amebae are differentiated from one another by the morphologic features of the trophozoite and cyst forms, such as the overall size, number of nuclei, nuclear chromatin pattern, and characteristics of the nuclear karyosome and cytoplasm. The flagellate *Dientamoeba fragilis* is also included in this chart as it has an ameboid appearance and would enter the differential diagnosis of amebae found in human stool specimens. From Pritt B (2014) *Parasitology Benchtop Reference Guide*. Northfield, IL: College of American Pathologists.

Trichomonas tenax

Trichomonas tenax, like *E. gingivalis*, is considered a commensal in the human oral cavity. Similarly, *T. tenax* has been associated with periodontal disease, but also like *E. gingivalis*, it is generally believed its presence under such conditions is associated with increased bacterial growth (Dubar et al., 2020). There is no specific pathologic response associated with *T. tenax* in the oral cavity, however its presence could be an indicator of periodontal disease caused by other etiologies (Marty et al., 2017). *Trichomonas tenax* has been associated with extra-oral disease, such as pleural empyema, but it is generally believed its presence in such sites is associated with bacteria present and *T. tenax* itself is not an agent of disease (Bellanger et al., 2008).

Diagnosis of *T. tenax* is made primarily by microscopy, either wet mount examinations or permanent smears stained with Giemsa or Wheatley's Trichrome (Marty et al., 2017). Trophozoites are 12–30 μ m long and ellipsoidal or ovoid in shape. Each has a single large nucleus, a prominent axostyle, and four anteriorly-directed flagella. Morphologically, it is very similar to *T. vaginalis* observed in urogenital specimens (Marty et al., 2017). There is no cyst stage.

Leishmania spp. (mucocutaneous leishmaniasis)

Biology and epidemiology

Leishmaniasis is a serious and often debilitating parasitic disease that is classified as a Neglected Tropical Disease by the WHO (WHO, 2020a). Leishmaniasis is caused by flagellated protozoa in the genus *Leishmania*; approximately 19 species of *Leishmania* have been implicated in human disease. There are three broad clinical categories of leishmaniasis: cutaneous leishmaniasis (CL), mucocutaneous leishmaniasis (MCL; also referred to as mucosal leishmaniasis), and visceral leishmaniasis (VL). MCL is caused by three species in the subgenus *Viannia*, including *L. (V.) guyanensis*, *L. (V.) panamensis*, *L. (V.) braziliensis*, as well as *L. amazonensis* which is in the subgenus *Leishmania* (David and Craft, 2009; Torres-Guerrero et al., 2017). All four species occur in tropical Central and South America. *Leishmania amazonensis* occurs in Brazil, Venezuela, and Bolivia. *Leishmania braziliensis* occurs in the Western Amazon Basin of Brazil, Venezuela, Bolivia, and Peru, and in Guatemala. *Leishmania guyanensis* is found in northern South America (French Guiana, Brazil, Suriname, and Bolivia). *Leishmania panamensis* occurs in Central and South America (Steverding, 2017).

Leishmaniasis is a vector-borne disease transmitted by sand flies in the genera *Phlebotomus* (Old World) and *Lutzomyia* (New World). Infection is initiated when infected sand flies introduce the motile (flagellated) promastigote stage of *Leishmania* intradermally when taking a blood meal. The promastigotes are taken up by primarily by macrophages, but also neutrophils and dendritic cells. Within macrophages, the parasites employ a variety of mechanisms to evade the microbicidal activities of the phagolysosome and convert it into a parasitophorous vacuole in which it can survive and multiply (Arango Duque and Descoteaux, 2015). Promastigotes transform into amastigotes, the small non-motile form of the parasite, and divide by binary fission. The infected cells migrate away from the bite site and carry the parasite to other organs, where they continue to replicate and infect other macrophages. Infected macrophages in the skin may be picked up by a new sand fly taking a blood meal, thus continuing the parasite lifecycle. Within the gut of the sand fly host, the amastigotes transform into promastigotes and migrate to the salivary glands, where they can infect another host during subsequent sand fly blood feeding.

Pathogenesis, clinical presentation, and treatment

Mucocutaneous leishmaniasis is a disseminated form of cutaneous infection resulting in metastasis from the original cutaneous lesion to the mucosa of the oro- and naso-pharynx (CDC, 2020a; Burza et al., 2018; Palumbo, 2010). Up to 90% of patients with MCL have a scar from previous CL. Mucosal involvement generally occurs within several years to decades of the initial cutaneous infection, and often begins with non-specific nasal symptoms such as epistaxis (nasal bleeding), rhinorrhea (runny nose), and nasal stuffiness. Lymphadenopathy is also common, and generally precedes ulceration (David and Craft, 2009). Systemic symptoms such as fever and hepatomegaly may also be present. Ulcerative lesions generally appear first on the lips or nostrils and expand to involve the palate and nasal septum (Burza et al., 2018; Palumbo, 2010). Over time, expansive tissue damage resulting from infiltrating infected macrophages and the associated host T-cell related cytotoxicity can result in life-threatening complications, including complete destruction of cartilaginous and soft tissue structures, airway obstruction and secondary infection (Fig. 2). Factors that determine the extent of the clinical manifestations of MCL include host cell-mediated immunity and virulence of the parasite (David and Craft, 2009).

Given the potential for severe, destructive disease, MCL should be treated aggressively using intravenous or intramuscular antimonial therapies (e.g., sodium stibogluconate), intravenous amphotericin, or oral miltefosine (CDC, 2020a; Palumbo, 2010; Medical Letter, 2013).

Diagnosis

MCL should be considered in all patients with an appropriate exposure history (i.e., sand fly bites in South or Central America) and ulcerative lesions of the oral/nasal mucosa, particularly when there is a history of prior cutaneous leishmaniasis (David and Craft,

Fig. 2 Moderately-advanced mucocutaneous leishmaniasis in a patient living in Paraguay. There is involvement of both nasal vestibules and erosion of his nasal septum. Courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

Fig. 3 *Leishmania* sp. amastigotes within the cytoplasm of a macrophage (Giemsa, 1000 ×). Each amastigote (arrow) has an eccentric nucleus and rod- to dot-shaped kinetoplast. The macrophage nucleus is denoted by an arrow head.

2009). Definitive diagnosis is by microscopy examination for intracellular and free amastigotes within tissue biopsies or aspirates. The amastigotes are small (2–4 μm), round to oval, and have an eccentric nucleus and rod-shaped kinetoplast (Fig. 3). The preferred microscopy preparation is Giemsa-stained impression preparations of sampled tissue. Histopathologic preparations can also be examined for the presence of amastigotes within the cytoplasm of macrophages, although the amastigotes are harder to identify due to the shrinkage that occurs during formalin fixation and tissue process. It is important to note the culture and/or NAAT offer greater sensitivity than microscopy and should be considered in cases where microscopy is non-diagnostic. The CDC provides diagnostic testing services for patients in the United States, including telediagnosis, culture, and NAAT (David and Craft, 2009).

Nematode infections

Gongylonema pulchrum (gongylonemiasis)

Gongylonema pulchrum is a parasite of livestock and other ruminants that has a nearly worldwide distribution. The parasite cycles between the vertebrate definitive host and an insect intermediate host, and human infection is acquired from the incidental (or intentional) ingestion of insects harboring infectious larvae (Libertin et al., 2017).

The most common clinical presentation of *Gongylonema* infection is the sensation of something moving in the oral mucosa and tongue (Allen and Esquela-Kerscher, 2013; Libertin et al., 2017). Nausea and vomiting are also common symptoms. Grossly, the oral mucosa shows an irregular “zigzag”-shaped blister-like lesion (Libertin et al., 2017). Removal of the worm is considered curative, although albendazole may be considered in patients with a heavier worm burden or prolonged duration of infection (Libertin et al., 2017).

Human infection of *G. pulchrum* is diagnosed by the identification of adult worms in the oral and esophageal mucosa, either by histopathology or extraction and examination of intact gross specimens. Rarely, eggs may be detected in wet mounts of stool. Adult female worms measure up to 14.0 cm while adult male worms measure up to 6.2 cm. Adults of both sexes have characteristic raised plaques (bosses) surrounding the anterior end of the worm (Naem et al., 2000). Eggs of *G. pulchrum* 50–70 μm long by 25–37 μm wide, have a thick shell, and are embryonated when shed in feces. The polar ends of the eggs often have a hyaline clearing (Ash and Orihel, 2007).

Anatrichosoma spp. (anatrichosomiasis)

Anatrichosoma is an enigmatic genus of nematodes related to the familiar human parasites *Trichuris trichiura* and *Trichinella spiralis*. Human infection is thought to be rare, with only three cases of human oral cavity involvement reported in the literature. All three cases were in patients living in the midwestern United States with recent travel to Mexico, and all were diagnosed by histopathologic examination of oral biopsies. *Anatrichosoma* species have not been morphologically described by histopathology, and therefore, the specific etiologic agents in these cases are not known. Based on the epidemiology, however, *A. buccalis*, a parasite of the oral cavity of opossums in the Americas, is the presumptive agent (Eberhard et al., 2014). The life cycle of *Anatrichosoma* species is not completely understood, but the history of the two most recent patients, a mother and daughter, participating in “snail facials” while on vacation in Mexico suggests the possible role of mollusks as an intermediate host (Eberhard et al., 2014). A second daughter participated in all of the same activities in Mexico with the exception of the snail facial and did not have any manifestations of infection.

Clinically, patients have presented with painful blisters on the tongue, lips, hard and soft palate, and oral mucosa. Grossly, raised track-like lesions and ulcerated lesions were also present at these sites (Eberhard et al., 2014, 2010). The patients' symptoms resolved following mebendazole or albendazole administration (Eberhard et al., 2014).

Diagnosis has been made by identifying adult worms in biopsy specimens of the oral mucosa and associated tissue. Worms in cross section will display typical trichuroid features such as bacillary bands and stichocytes (Eberhard et al., 2010). This morphologic appearance, in conjunction with the location, allows for the diagnosis of anatrchosomiasis.

Arthropod infections

Oral myiasis

Biology and epidemiology

Myiasis is colonization of living or dead animal tissue with fly larvae. Clinically, myiasis can be classified as obligatory (flies that have adapted to a parasitic lifestyle and require healthy host tissue), facultative (colonization of pre-existing wounds, often with dead or necrotic tissue), or accidental/incidental (incidental colonization of mucus membranes or biofilms on invasive medical devices, such as catheters) (Mathison and Pritt, 2014). The most common sites of infection in humans are the skin (furuncular myiasis), pre-existing, and often necrotic, wounds (facultative myiasis, wound myiasis), eyes (ophthalmomyiasis), and the ears, nose, and throat (ENT, cavitary myiasis) (Francesconi and Lupi, 2012). Oral myiasis has been reported worldwide, but is not common and is often seen in people with poor oral hygiene. Factors associated with oral myiasis include those that result in breaks in the oral mucosa (e.g. gingival disease, trauma, recent tooth extractions, malignancy) and those that result in prolonged mouth opening (e.g. mouth breathing while sleeping, alcoholism, dementia, intellectual disability, incapacitation). Infants who breastfeed from mothers with wound myiasis of the breast may also be at increased risk of oral myiasis (Francesconi and Lupi, 2012; Novo-Neto et al., 2015; Shikha et al., 2015).

Because oral myiasis usually involves infestation of pre-existing wounds and other unsanitary conditions, it is usually caused by species that normally cause facultative myiasis. One exception is the primary screwworm fly, *Cochliomyia hominivorax*, which will initially colonize a pre-existing wound but will continue to damage and consume healthy tissue. Other species implicated in oral myiasis include *Lucilia sericata*, *Wohlfahrtia magnifica*, *Musca domestica*, *Chrysomya bezziana*, *Oestrus ovis*, *Hypoderma bovis*, *H. tarandi*, *Gasterophilus intestinalis*, and *Calliphora vicina* (Francesconi and Lupi, 2012). Infection occurs when gravid female flies directly lay eggs (oviposition) or larvae (larviposition) on wounds and tissues.

Pathogenesis, clinical presentation, and treatment

Live maggots invade diseased, and occasionally healthy, tissue, causing pain and swelling in the affected area. Live maggots may be felt and seen within the tissue.

Treatment for oral myiasis is removal of larvae (Fig. 4) followed by cleaning of the wounds. Antibiotics may be prescribed to treat or prevent secondary bacterial infections (Shikha et al., 2015). Ivermectin has been shown to be effective in killing larvae by blocking the nerve impulses on nerve endings through the release of gamma amino butyric acid, which leads to paralysis and subsequent death of the larvae (Shikha et al., 2015).

Diagnosis

Diagnosis of oral myiasis is made by the gross examination of extracted fly larvae. Because removal of the larvae is curative, a definitive identification is not necessary. However, myiasis-causing fly larvae are often sent for identification for educational

Fig. 4 *Lucilia* sp. third instar larva. *Lucilia* sp. cause facultative wound myiasis and have been reported to cause oral myiasis. The dark, sclerotized, hook-like mandibles can be seen at the upper left of the image. This is the anterior portion of the larva, and the end that embeds into tissue while feeding. The posterior end (right) remains in contact with the environment to allow for respiration through two spiracles. Characteristics of the spiracular plate (inset) are used in the identification of the larva. From Mathison BA and Pritt B (2015) Arthropod Benchtop Reference Guide. Northfield, IL: College of American Pathologists.

purposes, scientific curiosity, and epidemiologic data. Identification of fly larvae to the genus or species level can be challenging, and best left to experienced parasitologists or entomologists. Helpful morphologic features include the arrangement of cuticular spines, shape of mandibles, and form of anterior and posterior spiracles and spiracular plates (Mathison and Pritt, 2015, 2014).

Parasites of the esophagus and stomach

As with the oral cavity, there are only a small number parasites that involve the esophagus and stomach (Table 2). While parasitic involvement of these regions is not usually life-threatening, infections can result in extensive morbidity and loss of productivity.

Protozoan infections

Trypanosoma cruzi (chagasic achalasia/chagasic megaesophagus)

Biology and epidemiology

Chagas disease, also known as American trypanosomiasis, is caused by the hemoflagellate *Trypanosoma cruzi*, which is endemic the New World, from the southern US to South America. In the natural life cycle, the parasite is transmitted to a mammalian host via the feces of an infected triatomine (kissing) bug (Fig. 5A). Efficient vectors of *T. cruzi* defecate while taking a blood meal from a human host. When the person scratches the bite site in response to an inflammatory response to the bug's bite, metacyclic trypomastigotes in the feces of the bug are rubbed into the wound. These metacyclic trypomastigotes invade surrounding tissues and transform into amastigotes that divide by binary fission. After about 4 days, the amastigotes transform into trypomastigotes and the host cells rupture, releasing these trypomastigotes into circulation (Fig. 5B). The trypomastigotes travel via the bloodstream to other tissues and initiate new replicative cycles. Without treatment, the infection can last for the lifetime of the patient (Bern et al., 2011). Humans can also be infected with *T. cruzi* by blood transfusion, organ donation, congenital transmission, and the ingestion of unpasteurized fruit and sugar cane juice contaminated with bugs and their feces (Bern et al., 2011).

Although Chagas disease is endemic only to the New World, international travel has made it a global concern (Connors et al., 2016). It is estimated that 6–7 million people are infected worldwide, with over 300,000 infected patients in the United States (CDC, 2020b; WHO, 2020a). The vast majority of these infections are believed to be in immigrants from endemic areas, although rare cases of locally-acquired infection have been reported in the southern United States (Bennett et al., 2018; Kuehn, 2016).

Chagas disease can be divided into acute and chronic forms of disease. Patients are thought to remain infected indefinitely, and approximately 20–30% of patients will go on to develop manifestations of chronic disease. The most common organ affected is the heart, with the GI tract being the second most common (CDC, 2019). The focus of this section is on the gastrointestinal manifestations associated with chronic Chagas disease.

Pathogenesis, clinical presentation, and treatment

Trypanosoma cruzi infection results in damage to the enteric nervous system, leading to various gastrointestinal motor disorders (e.g., altered peristalsis, failure of smooth muscle to relax) and “mega” syndromes (megaesophagus, megastomach, megaduodenum, megajejunum, megagallbladder, and megacolon) (Matsuda et al., 2009). Megacolon is the most commonly associated GI manifestation, and is associated primarily with chronic constipation. The esophagus is the second most common organ to be involved in GI Chagas disease, and results in achalasia (failure of the lower esophageal sphincter to relax), and resultant chagasic megaesophagus. The inability to pass food from the esophagus into the stomach leads to dysphagia, malnutrition, and severe weight loss (Matsuda et al., 2009).

Fig. 5 (A) A triatomine bug, *Triatoma pallidipennis*, capable of transmitting *Trypanosoma cruzi*, the causative agent of Chagas disease. Note the bug's large size and prominent ornamentation. (B) Trypomastigote stage of *Trypanosoma cruzi* in a Giemsa-stained peripheral blood smear (1000 $\times$). Note the large kinetoplast at the posterior end of the organism (arrow). (A) Courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

Treatment varies by the stage of disease, age of the patient, and presence of cardiomyopathy. Antiparasitic treatment with benznidazole or nifurtimox is strongly recommended for all children with chronic infection, as well as adults ≤ 50 years with chronic infection and no evidence of advanced cardiomyopathy. In older patients, and those with cardiomyopathy, the decision to give antiparasitic therapy must be considered on a case-by-case basis, considering the patient's clinical status, preference for treatment, and overall health (CDC, 2019). In cases of achalasia, surgical or medical interventions may also be indicated to relax the lower esophageal sphincter and improve esophageal emptying (Matsuda et al., 2009).

Diagnosis

The primary means of diagnosing chronic Chagas disease is by antibody detection. Unfortunately, immunodiagnosis of Chagas disease is challenging due to modest sensitivity and specificity provided by any single assay (Afonso et al., 2012). In some parts of the world, including the US, it is common to run two assays concurrently, or to screen with an assay that has high sensitivity, such as an enzyme-linked immunosorbent assay (EIA), and then confirm with an assay with greater specificity, such as immunoblot (Whitman et al., 2019). The CDC (Atlanta, Georgia, USA) uses the Chagatest-ELISA (Weiner lab Group, Rosario, Argentina) alongside an immunoblot using trypomastigote excreted-secretory antigens (TESA). An immunofluorescence assay (IFA) can be used as a tie-breaker when results are discordant (<https://www.cdc.gov/dpdx/trypanosomiasisamerican/index.html>). Antibody detection methods are also used for screening blood donors.

Tissue biopsy for microscopy and/or NAAT may be useful for detecting parasites in cardiac biopsies, but has limited utility in diagnosing GI Chagas disease. Amastigotes are rarely seen within GI tissues, except in profoundly immunocompromised patients (Meyers et al., 2011).

Unlike cardiac disease, amastigotes are not usually seen in biopsies of the GI tract in patients with Chagas disease.

Nematode infections

Anisakis spp., *Pseudoterranova spp.*, and *Contracaecum spp.* (anisakiasis)

Biology and epidemiology

Anisakiasis is a zoonotic disease caused by nematodes in the genera *Anisakis*, *Pseudoterranova*, and *Contracaecum*. The natural definitive hosts for these anisakid nematodes are fish-eating marine mammals and birds, where the larvae develop into adults in the gastric mucosa. Fully-embryonated eggs (eggs containing an infectious third-instar, or L3, larva) are shed in the feces of the definitive host and hatch in marine and brackish water. The L3 larvae then infect a crustacean intermediate host, which is in turn eaten by a fish or squid that serves as a paratenic host. The worms become encapsulated in the flesh of the fish or squid and the definitive host becomes infected after eating a paratenic host (Ortega and Sterling, 2017; Xiao et al., 2015). Humans also become infected after eating raw or undercooked paratenic hosts. However, humans are a dead-end host for anisakid nematodes as the worms cannot develop to sexual maturity. Human infection is usually confined to the gastrointestinal tract, but ectopic anisakiasis can occur when worms penetrate the gastric or intestinal mucosa and enter the peritoneal cavity. Ectopic disease has been reported to involve the mesentery, omentum, mesocolic lymph nodes, spleen, pleural cavity, and parametrium (Ramanan et al., 2013).

Human anisakiasis is most common in parts of the world where raw or undercooked fish is eaten as part of the cultural norm, most notably in Japan, coastal western Europe and South America, and in recent decades, North America (Audicana and Kennedy, 2008; Ramanan et al., 2013), although the disease can occur almost anywhere due to the global seafood trade. Commonly implicated dishes include sushi, sashimi, and ceviche. Anisakid nematodes generally have low host specificity for the piscine and molluscan hosts, and some of the most common commercial marine fish and squid may serve as paratenic hosts, including salmon, cod, snapper, herring, tuna, grouper, and Japanese flying squid (Fig. 6) (Ortega and Sterling, 2017). Therefore, a variety of fish and

Fig. 6 Coiled anisakid (*Pseudoterranova* sp.) larvae in a fresh cod fillet. The inset shows a the size of the anisakid larva following removal from the fillet. From Mathison BA and Pritt BS (2018) Chapter 5: Parasitic diseases. In: Atlas of Fundamental Infectious Diseases Histopathology: A Guide for Daily Practice. Pritt BS (ed.). Northfield, IL: College of American Pathologists.

squid may pose a risk of anisakiasis if not fully cooked before ingestion. The U.S. Food and Drug Administration (FDA) recommends freezing fish at -20°C for 7 days or -35°C for 15 h to kill parasites prior to serving raw (FDA, 2020).

Pathogenesis, clinical presentation, and treatment

Clinical manifestations of anisakiasis are due to the presence of the live worm and/or the host immune response to larval antigens (Ramanan et al., 2013). The infection may come to the patient's attention when the larva is expelled through the mouth or nose. Of greater concern is when the larva burrows into the gastric or intestinal mucosa, which results in acute onset of epigastric or abdominal pain, respectively. Nausea, vomiting, and diarrhea are also common in this setting. Acute gastric symptoms typically occur within a few hours of ingesting the larva in undercooked seafood, whereas acute intestinal anisakiasis presents approximately 5–7 days after ingestion (Ramanan et al., 2013). If the larva is not immediately retrieved, chronic gastric or intestinal symptoms may occur as a result of the inflammatory reaction to the dying worm. If the larva penetrates the wall of the stomach or intestine, then peritonitis may occur. Additional symptoms may also be associated with the presence of the larva in the ectopic location. Removal of the embedded larva via endoscopy or surgery is curative.

Allergic reactions may be observed in susceptible individuals following exposure to anisakid allergens from either live or dead worms. Manifestations range from mild urticaria to life-threatening anaphylactic shock (Audicana et al., 2002; Audicana and Kennedy, 2008). Patients with severe allergies are advised to permanently avoid ingesting seafood products that may contain anisakid larvae. Treatment may include antihistamines and epinephrine.

Diagnosis

Anisakiasis is diagnosed based on the clinical presentation and exposure history, followed by confirmatory laboratory testing. When worms are expelled live from the nose or mouth, diagnosis is made by the morphologic identification of the intact L3 larvae. Grossly, L3 anisakid larvae resemble small specimens of *Ascaris lumbricoides*, measuring 10–50 mm long and possessing three fleshy anterior 'lips' (Fig. 11). Anisakids can be differentiated from *A. lumbricoides* from the presence of a boring tooth near the buccal opening or a terminal mucron, a small spine-like process which can be found in all species of *Pseudoterranova*, but only in some species of *Anisakis* and never in *Contracaecum* (Meyers et al., 2000). Worms embedded in the gastric or intestinal mucosa can be removed via endoscopy and identified grossly, or identified in biopsy specimens processed by histopathology. Anisakids can be identified to the genus level by examining structures of their alimentary canal and lateral chords, however a genus-level identification is not needed for patient management, as removal is curative (Meyers et al., 2000, Ortega and Sterling, 2017).

Diagnosis of ectopic anisakiasis is usually based on the incidental finding of dead, sometimes calcified, worms in biopsy specimens that were collected based on the suspicion of other etiologies, such as tumors (Mathison and Pritt, 2018a). The worms can usually be identified by the characteristics of the musculature, lateral chords, and the absence of sexual structures (Mathison and Pritt, 2018a). Degrading worms may be difficult to distinguish from ectopic *Ascaris lumbricoides*, the latter of which may possess sexual structures and eggs, which would not be present in anisakid larvae (Mathison and Pritt, 2018a).

Diagnosis of allergic reactions to anisakid nematodes is initially performed by a positive skin prick test in conjunction with compatible clinical manifestations and a recent history of eating fish or shellfish. The skin prick test should be confirmed by specific IgE antibodies using an additional assay (e.g. radioimmunoassay) in conjunction with a lack of antibodies to the host fish proteins (Audicana et al., 2002).

Serologic assays that detect parasite specific IgE are commercially-available at select reference and public health laboratories. There are no widely available molecular assays for routine clinical diagnosis of anisakiasis, and such tests are only likely to be offered by specialized reference laboratories.

Parasites of the small intestine

A large number of protozoa and helminths are capable of infecting the small intestine, and they are associated with a significant amount of human morbidity (Table 3). While some infections are rarely fatal (e.g., cryptosporidiosis, trichostrongylosis, cestode infections), others are important causes of global mortality (e.g., strongyloides hyperinfection, ascariasis with small bowel obstruction, hookworm infection with severe anemia, intestinal capillariasis).

Protozoan infections

Giardia duodenalis (giardiasis)

Biology and epidemiology

Giardia duodenalis (syn. *G. intestinalis*, *G. lamblia*) is a cosmopolitan flagellated protozoan parasite, with higher prevalence rates reported in regions with poor sanitation. There are eight genetic assemblages of *G. duodenalis*, two of which (A and B) are parasites of both humans and animals and have been implicated in both person-to-person transmission and zoonotic infections. The remaining six assemblages (C–H) exhibit some degree of host specificity for non-human animals and do not cause disease in humans (Ryan and Caccio, 2013). The WHO estimates that *G. duodenalis* caused 183,842,615 illnesses in 2010, but fortunately, no associated deaths were noted (Kirk et al., 2015). In resource-rich regions with adequate sanitation, infection is commonly associated with ingestion of untreated surface water (e.g., by hikers, campers) and in institutional settings (e.g., daycare, institutions for intellectually disabled individuals). Water- and food-borne outbreaks have also been reported (Adam et al., 2016).

Fig. 7 Scanning electron microscopic images of a single *Giardia duodenalis* trophozoite (left) and numerous *G. duodenalis* trophozoites attached to the duodenal mucosa (right). Courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

Giardia duodenalis has a simple one-host life cycle. Infection occurs from the ingestion of mature cysts in fecally-contaminated water, or, less-commonly, food and fomites. The parasite excysts in the duodenum to produce two trophozoites. Trophozoites replicate by binary fission in the small intestine and feed on the surface of the intestinal mucosa (Figs. 7 and 8). After exposure to biliary fluid in the jejunum, some trophozoites form cysts and are excreted in the feces along with trophozoites. While both cysts and trophozoites are shed in feces, only cysts are infectious for a new host (Adam, 2001). Giardiasis is also regarded as a sexually-transmitted infection (STI) and parasites can pass between sexual partners via the anal-oral route (Escobedo et al., 2014).

Pathogenesis, clinical presentation, and treatment

Many patients with giardiasis are asymptomatic, particularly in endemic settings. When present, common symptoms include profuse, foul-smelling, watery diarrhea, flatulence, belching, bloating, vomiting, and weight loss. Less commonly, low grade fever and urticaria may also be present. Symptoms usually occur following an incubation period of 1–2 weeks, and usually last for 1–4 weeks. Many patients experience full resolution of symptoms. However, chronic giardiasis may occur, and has been reported in up to 50% of patients. Patients with chronic giardiasis often experience loose stools, malabsorption, flatulence, weight loss, and cramping. These symptoms may wax and wane over a period of several months. Some patients may also develop lactose intolerance.

Giardia does not invade into the intestinal wall, but adheres to the mucosal surface using its ventral sucking disc. In this way, it is thought to lead to the structural and functional abnormalities of the intestinal lining that result in the symptoms of giardiasis. Treatment is with metronidazole, tinidazole, or nitazoxanide. Rehydration may also be necessary.

(Lalle and Hanevik, 2018) Diagnosis

Diagnosis of giardiasis has historically been performed by O&P examination of stool and duodenal aspirates. Today there are numerous commercial antigen detection assays and NAATs for the diagnosis of giardiasis with improved sensitivity and susceptibility over microscopy.

Microscopy

Both cysts and trophozoites of *G. duodenalis* can be detected in O&P examinations of stool and duodenal aspirates. Because organisms are shed sporadically, multiple stools may need to be examined to ensure an accurate diagnosis. In fresh, unpreserved stool, living trophozoites may be detected in a saline wet mount preparation. *Giardia duodenalis* moves in a liquid substrate with a fluttering-like motion referred to as “falling leaf” motility. In preserved stool, both cysts and trophozoites may be detected in both wet mount concentrations and permanent-stained smears. Trophozoites are pyriform (pear-shaped) and measure 10–20 µm long (Fig. 7). They possess two large nuclei, a large sucking disc occupying the ventral surface of the anterior portion of the body, and prominent curved median bodies. Trophozoites possess eight flagella, although these are often not readily visible in routine permanent-stained slides (Fig. 8). Cysts are ovoid in shape and measure 8–19 µm in length. Mature cysts have four nuclei, axostyles, and curved median bodies (Fig. 8). The cytoplasm may be pulled away from the cyst wall, creating a halo-like effect (Ash and Orihel, 2007).

Occasionally, giardiasis is diagnosed by histopathologic examination of duodenal biopsies, particularly in chronic cases in which giardiasis is not suspected. Classic features include flattened duodenal villi and associated trophozoites (Mathison and Pritt, 2018a).

Antigen detection

There are many commercial assays available for the detection of *G. duodenalis* in stool and duodenal aspirates, some of which can be used for the simultaneous detection of *Cryptosporidium* and *Entamoeba histolytica*. Some assays require fresh, unpreserved stool while others can be performed using stool in fixatives. Also, some assays may not detect both cysts and trophozoites (Cama and Mathison, 2015; García et al., 2018). Available formats include lateral flow immunochromatography, enzyme immune assay, and direct fluorescence antigen detection, the latter of which is considered the gold standard method.

NAATs

There are several commercial NAATs available for the detection of *G. duodenalis* and other intestinal parasites. Some labs also employ on LDTs, often only targeting specific organisms for confirmation after morphological analysis. There are several multiplex NAATs for the detection of *G. duodenalis*, as well as other intestinal protozoa, three of which are FDA-approved for use in the US: (1) BioFire® FilmArray® Gastrointestinal GI Panel (BioMérieux, Marcy-l'Étoile, France), (2) BD MAX™ Enteric Parasite Panel (Becton Dickinson, Franklin Lakes, NJ), and (3) xTag® Gastrointestinal Pathogen Panel (Luminex, Austin, TX). In addition, there are several assays with CE approval but are not FDA-approved for use in the US.

Cryptosporidium spp. (cryptosporidiosis)

Biology and epidemiology

Cryptosporidiosis is caused by apicomplexan parasites in the genus *Cryptosporidium*. Historically, *Cryptosporidium* was classified among the coccidians, such as *Cyclospora cayetanensis* and *Toxoplasma gondii*. However, molecular and morphologic analyses place *Cryptosporidium* among the gregarines within Apicomplexa (Ryan et al., 2016). In the clinical realm, however, *Cryptosporidium* is still often referred to as a coccidian for familiarity and ease of communication, and because it is diagnosed by the same staining methods used for the “true” coccidians. At least 16 species of *Cryptosporidium* have been implicated in human infection, although the vast majority of cases are caused by two species: *C. hominis*, an anthropophilic species that only infects humans, and *C. parvum*, a parasite of livestock and other ruminants that causes zoonotic disease in humans. Both species are ubiquitous worldwide and infection is usually associated with contaminated water, although foodborne and direct person-to-person infection is possible (Cama and Mathison, 2015). *Cryptosporidium* infection can be a common cause of diarrheal disease in resource-limited parts of the world (Korpe et al., 2018). The WHO estimates that *Cryptosporidium* spp. caused 64,003,709 illnesses in 2010, with 27,553 deaths (Kirk et al., 2015). In resource-rich societies with adequate sanitation, infection is most commonly associated with exposure to recreational waters (natural sources of freshwater, public swimming pools, water parks, splash pads), the consumption of undercooked or raw food or unpasteurized milk and fruit juices, animal contact at petting zoos and fairs, and in day care centers (Cama and Mathison, 2015; Conrad et al., 2017; Turabelidze et al., 2007). Cryptosporidiosis can be classified as an STI, especially in MSM (Danila et al., 2014). *Cryptosporidium* has a complex life cycle involving both sexual and asexual reproduction in a single host. Infection is initiated by the ingestion of fully-sporulated oocysts in fecal-contaminated water, food, and fomites. Oocysts excyst in the upper small intestine and release sporozoites that infect the intestinal epithelial cells. The parasites form a parasitophorous vacuole between the host cell membrane and cytoplasm and derives nutrients from the host cell by means of a feeder organelle.

Fig. 9 Relative size of *Cryptosporidium* spp. and coccidia oocysts as seen by modified acid fast stain (1000 $\times$). Microsporidia spores are also shown for size comparison (chromotrope 2R stain). While once thought to be parasites, microsporidia are now known to be highly-specialized fungi. From Pritt B (2014) *Parasitology Benchtop Reference Guide*. Northfield, IL: College of American Pathologists.

Within the parasitophorous vacuole, sporozoites undergo cycles of asexual reproduction (merogony). Mature meronts rupture from the host cell and take one of two pathways. Type I meronts infect surrounding host cells and perpetuate the asexual cycle, while Type II meronts give rise to microgametes and macrogametes that initiate the sexual cycle (gametogony). Fertilization results in the formation of zygotes. Zygotes differentiate into oocysts that contain four naked (lacking a sporocyst wall) sporozoites. There are two kinds of oocysts produced: thin-walled oocysts rupture in the lumen of the intestinal tract and infect neighboring cells (autoinfection); thick-walled oocysts are shed via the feces into the environment to infect a new host (Fig. 9). Oocysts of *Cryptosporidium* are shed fully-sporulated and are infectious immediately out of the host (Cama and Mathison, 2015).

Pathogenesis, clinical presentation, and treatment

Cryptosporidiosis may have a range of manifestations, from asymptomatic infection, to mild diarrhea, to persistent, life-threatening disease (Bouzid et al., 2013). When present, symptoms are thought to be due to the parasites' interference with normal small intestinal secretory and absorptive functions, either through direct injury by the parasite or the resultant host immune response (Bouzid et al., 2013).

The extent and outcome of infection are largely dependent on the host's immune status and parasite-specific virulence factors. Immunocompetent individuals generally present with profuse watery, and occasionally prolonged, diarrhea, as well as nausea, vomiting, abdominal pain, and/or low-grade fever. Non-specific systemic symptoms including myalgia, headache, malaise and anorexia may also be present. Infection will generally resolve in 2–3 weeks, and illness may be shortened with the antiparasitic agent, nitazoxanide (Medical Letter, 2013). Infection may be more severe in immunocompromised hosts, particularly patients with HIV/AIDS and CD 4 T lymphocyte cell counts of less with 50 cells/mm³ (Bouzid et al., 2013). These patients may experience prolonged diarrhea, dehydration, anorexia and wasting, as well as biliary tract disease, pancreatitis, and rarely, involvement of the respiratory tract. Unfortunately, there is currently no effective antiparasitic therapy for cryptosporidiosis in profoundly immunocompromised patients (Medical Letter, 2013). Immune reconstitution (e.g., stopping immunosuppressive therapies, administering antiretrovirals for patients with AIDs) should be considered for severe, unremitting cases.

Diagnosis

Diagnosis of cryptosporidiosis can be performed by microscopy, antigen detection, and NAATs.

Microscopy

Cryptosporidium is not easily detected by traditional O&P examination as the oocysts do not stain well with Wheatley's trichrome or iron hematoxylin stains. The visualization of oocysts in stool specimens is enhanced by the use of special stains, such as Kinyoun's modified acid-fast (MAF) (Fig. 9), Ziehl-Neelsen acid-fast, aurimine O, and modified safranin (Cama and Mathison, 2015). Oocysts of *Cryptosporidium* are 4–6 μ m in diameter; they possess a thick outer wall and contain four sporozoites which may be visible in stained smears (Ash and Orihel, 2007). The different species of *Cryptosporidium* cannot be separated by morphology, but a species-level identification is not needed for clinical management. Unlike the true coccidians *Cyclospora*, *Cystoisospora*, and *Sarcocystis*, oocysts of *Cryptosporidium* do not autofluorescence under UV light.

Occasionally, cryptosporidiosis is diagnosed by histopathologic examination of duodenal biopsies, particularly in chronic cases in which infection is not suspected. The parasites can be seen within the small intestinal brush border as small (3–5 µm), spherical, blue-purple objects. Microvillous atrophy and mild inflammation may also be noted (Mathison and Pritt, 2018a).

Antigen detection

As with giardiasis, there are many commercial antigen detection assays available for the detection of *Cryptosporidium*, with an increased sensitivity over morphologic analysis. Some of the assays allow for concurrent diagnosis of giardiasis and amebiasis. There are several different methods, including DFA, EIA, and lateral flow assays (LFA), and for the most part the sensitivity and specificity is similar among the various platforms. For most assays, fresh, frozen, and formalin-preserved stool is acceptable for testing (Garcia et al., 2018).

NAATs

For routine clinical diagnosis and screening, many commercial multiplex assays for *G. duodenalis* will also detect *Cryptosporidium* spp., and with increased sensitivity and specificity over both morphologic analysis and antigen detection.

NAATs and sequence analysis can also be used for species-level identification. While this extent of identification is not important for clinical patient management, it can be very useful for outbreak investigations and in better understanding the molecular epidemiology of cryptosporidiosis. Genotyping has become a useful tool in identifying species and strains of *Cryptosporidium*. In the United States, for example, the CDC has developed *CryptoNet* (<https://www.cdc.gov/parasites/crypto/cryptonet.html>), a multi-disciplinary, molecular-based surveillance system to identify clusters and outbreaks in the US. Many European countries have their own local surveillance systems (Morris et al., 2019). Historically, genotyping was performed by using conventional PCR in combination with either restriction fragment length polymorphism (RFLP) or Sanger sequencing analysis (Xiao and Feng, 2017). Multilocus genotyping has shown some potential in outbreak investigations, but for it to be successful, would require a standardized typing scheme across multiple agencies and disciplines. While whole genome sequencing has had success for bacterial diseases, it is probably a while before it could be used for *Cryptosporidium* (Morris et al., 2019).

Cyclospora cayetanensis (cyclosporiasis)

Biology and epidemiology

Cyclosporiasis is caused by the intestinal coccidian *Cyclospora cayetanensis*. While other species of *Cyclospora* have been identified from non-human primates (Eberhard et al., 1999), *C. cayetanensis* is the only species to have been recorded from humans, and humans are believed to be the only host for *C. cayetanensis* (Cama and Mathison, 2015). Cyclosporiasis is primarily a disease of the tropics and subtropics and areas of endemicity include Central and South America, parts of the Middle East (Egypt and Turkey), the Indian subcontinent (including Nepal), southeast Asia, and Indonesia (Almeria et al., 2019). In the United States, cyclosporiasis is a seasonal illness and most infectious occurring from May to August; vehicles of transmission are primarily fresh produced imported from Latin America (Casillas et al., 2019).

Cyclospora cayetanensis has a life cycle similar to *Cryptosporidium*, with some important caveats. Infection occurs from the ingestion of fully-sporulated oocysts, usually on fresh produce contaminated with infected water. In the small intestine, oocysts release two sporozoites, each containing two infectious sporozoites. Sporozoites infect intestinal epithelial cells and form a parasitophorous vacuole in the cytoplasm of the host cell. As with *Cryptosporidium*, the parasite undergoes cycles of asexual and sexual reproduction, eventually leading to the production of oocysts (Fig. 9). Unlike with cryptosporidiosis, oocysts of *Cyclospora* are shed into the environment unsporulated. Factors accounting for sporulation and infectivity are not well understood, but are believed to include temperature, humidity, and possibly sunlight exposure. In the environment, sporulation takes on average 1–2 weeks (Cama and Mathison, 2015). Given that the oocysts must mature in the environment before they become infectious, direct person-to-person spread is not seen with cyclosporiasis. Instead, infection is only acquired via ingestion of oocysts from the environment in fecally-contaminated food or water. Also, there are no animal reservoirs. Therefore, infection can be prevented by providing adequate sanitation facilities and keeping human waste out of soil and water where crops are grown for human consumption.

Pathogenesis, clinical presentation, and treatment

Cyclospora cayetanensis infection results in acute and chronic inflammation, reactive vascular changes in the intestinal mucosa, and partial atrophy of the intestinal villi, leading to disruption of the intestinal barrier and malabsorption. Resultant symptoms commonly include watery diarrhea, abdominal pain, nausea, anorexia, weight loss and low-grade fever being commonly-reported symptoms (Ortega and Sanchez, 2010). Occasionally, the diarrhea may contain mucus or blood. Most patient living in non-endemic settings experience symptoms, while asymptomatic cases are more frequent in endemic settings. Patients at risk for severe disease include the very young, very old, and patients with AIDS. If untreated, these patients may experience life-threatening dehydration and wasting (Ortega and Sanchez, 2010). Biliary disease has also been reported, primarily in patients with AIDS. Treatment is recommended in all patients to shorten the duration of symptoms, which can otherwise last for weeks to months. The antiparasitic treatment of choice is trimethoprim-sulfamethoxazole (Ortega and Sanchez, 2010, Medical Letter, 2013).

Diagnosis

The diagnosis of cyclosporiasis is made primarily by microscopy. Molecular diagnosis is improving, but there are currently no antigen-detection assays for routine clinical diagnosis.

Microscopy

As with *Cryptosporidium*, oocysts of *C. cayetanensis* do not take up traditional stool permanent stains and are not as easily detected by traditional O&P examination. The preferred staining methods for *C. cayetanensis* are Kinyoun's modified acid-fast and modified safranin, which both stain the oocysts bright pink-red (Fig. 9). In specimens stained with MAF, the parasite exhibits irregular staining patterns and many oocysts may fail to take up the stain ("ghost forms"). The hot safranin method may provide more uniform staining (Cama and Mathison, 2015; Visvesvara et al., 1997). Oocysts of *C. cayetanensis* are consistently larger than those of *Cryptosporidium*, measuring 8.0–10.0 µm in diameter. The oocysts do not possess sporozoites in freshly-collected stool specimens. The oocyst is refractile and exhibits a "ground-glass" appearance (this feature is best observed in ghost forms); the outer wall may be folded or collapsed (Cama and Mathison, 2015; Ash and Orihel, 2007).

An interesting biological phenomenon of *C. cayetanensis* is the ability of its oocysts to autofluoresce when wet mounts are examined under UV illumination. The oocyst wall will fluoresce blue when examined with an excitation filter of 330–365 nm, and exhibit a less intense fluorescence when examined with an excitation filter of 450–490 nm (Cama and Mathison, 2015). Suspicious objects observed in the wet mount of an O&P examination can be easily confirmed by examining the specimen under UV illumination with an appropriate filter. However, iodine used in O&P exams is inhibitory to the autofluorescence, so if iodine is used routinely, a fresh wet mount without iodine should be prepared.

Occasionally, cyclosporiasis is diagnosed by histopathologic examination of small intestinal biopsies, particularly in chronic cases in which infection is not suspected. Various forms parasites can be seen within parasitophorous vacuoles in epithelial cells (Mathison and Pritt, 2018a).

NAATs

Currently, there only two multiplex assays for the clinical diagnosis of cyclosporiasis, the BioFire™ FilmArray™ GI Panel, which has both FDA and CE approval, and the Seegene Allplex Gastrointestinal Panel, which only has CE approval. These multiplex panels detect *C. cayetanensis* as well as other common bacterial, viral and parasitic causes of diarrhea.

Unlike with *Cryptosporidium*, the use of genotyping for outbreak investigations of cyclosporiasis is still in its infancy. Several genetic markers have been studied as potential tool for cluster and outbreak investigations, including single-nucleotide polymorphisms and small insertions and deletions spanning the apicoplast genome (Cinar et al., 2016) and the mitochondrial junction region (Nascimento et al., 2019). Most recently, sequencing analysis of the complete mitochondrial genome shows potential for linking cases during outbreaks (Cinar et al., 2020).

Cystoisospora belli (cystoisosporiasis)

Biology and epidemiology

Cystoisosporiasis is a coccidian infection caused by *Cystoisospora belli*. Historically placed in the genus *Isospora*, morphologic and molecular data support the exclusion of *C. belli* (and all historical *Isospora* parasites of mammalian hosts) from *Isospora*, which, as currently delineated, are parasites of birds (Barta et al., 2005). *Cystoisospora belli* has a worldwide distribution, but most human cases are seen in the tropics and subtropics of Central and South America, the Caribbean, Africa, and Southeast Asia. Most cases seen in the US and Europe are in travelers that have visited, or immigrants from, endemic areas, especially those that are immunocompromised (Dubey and Almeria, 2019).

The life cycle of *C. belli* is very similar to that of *C. cayetanensis*. Infection occurs from the ingestion of fully-sporulated oocysts, usually in contaminated food, water, and fomites. In the small intestine, oocysts release two sporocysts, each containing four infectious sporozoites. Sporozoites infect intestinal epithelial cells and form a parasitophorous vacuole in the cytoplasm of the host cell. As with *C. cayetanensis*, the parasite undergoes cycles of asexual and sexual reproduction, eventually leading to the production of oocysts which are shed unsporulated or partially sporulated into the environment via the feces (Fig. 9), (Cama and Mathison, 2015).

Pathogenesis, clinical presentation, and treatment

Like cryptosporidiosis and cyclosporiasis, cystoisosporiasis is associated with disruption of the intestinal barrier and malabsorption (Lindsay and Weiss, 2011). Patients generally presents with profuse watery diarrhea, abdominal pain, nausea, vomiting, and low grade fever (Dubey and Almeria, 2019). Steatorrhea and acalculous cholecystitis may also occur. Infection is generally self-limited, but may be severe, prolonged and life-threatening in immunocompromised patients such as those with AIDS. Treatment is with trimethoprim-sulfamethoxazole (Medical Letter, 2013).

Diagnosis

Cystoisosporiasis is diagnosed primarily by microscopy, either by traditional stool examinations, or less commonly, histopathology. Because of the large size of the oocysts, *C. belli* is more easily recognized in traditional O&P examinations. However, oocysts are shed in much smaller numbers than *Cryptosporidium* and *C. cayetanensis*, so multiple wet mounts may need to be examined. If permanent stains are used in diagnosis, Kinyoun's MAF and modified safranin are preferred over Wheatley's trichrome. The oocyst wall and developing sporoblast(s) will autofluoresce when examined under UV illumination with a proper excitation filter (see under *Cyclospora cayetanensis*, above) (Cama and Mathison, 2015). When observed in wet mounts, oocysts of *C. belli* are 20–33 µm long by 10–19 µm wide, ellipsoidal in shape, and possess one or two immature sporoblasts (Fig. 9). Oocysts in patients who have been treated may appear devoid of sporocysts (Ash and Orihel, 2007).

Occasionally, cystoisosporiasis is diagnosed by histopathologic examination of small intestinal biopsies, particularly in chronic cases in which infection is not suspected. Several asexual and sexual developmental stages of *C. belli* can be observed in biopsy specimens of the intestinal epithelium. Parasitophorous vacuoles tend to be located more basal in the cytoplasm of the epithelial cell, as compared to *C. cayetanensis* which tends to be located closer to the apical margin (Mathison and Pritt, 2018a). In AIDS patients, *Cystoisospora belli* can be observed outside the intestinal epithelium, such as in mesenteric lymph nodes. Although *C. belli* can infect the gallbladder mucosa, several recent reports of gall bladder involvement with *C. belli* in immunocompetent patients are now believed to represent misidentification of non-parasitic epithelial inclusions (Dubey and Almeria, 2019; Swanson et al., 2018).

Of note, *C. belli* infection may elicit a peripheral eosinophilia, which is not of feature of most other intestinal protozoal infections. The other protozoan parasites associated with peripheral eosinophilia are *Sarcocystis* spp. (intestinal and muscular forms of disease) and *Dientamoeba fragilis* (see below).

Sarcocystis hominis, S. suihominis (intestinal sarcocystosis)

There are two clinical diseases associated with coccidians in the genus *Sarcocystis*: intestinal sarcocystosis, which is caused by *S. hominis* and *S. suihominis*, and muscular sarcocystosis, which is caused by zoonotic species of *Sarcocystis*. The focus of this chapter will be intestinal sarcocystosis.

Biology and epidemiology

Sarcocystis spp. have a complex two-host life cycle. Humans are the natural definitive host for *S. hominis* and *S. suihominis* and infection occurs nearly worldwide (Fayer et al., 2015). Humans become infected after the ingestion of undercooked beef (*S. hominis*) or pork (*S. suihominis*) harboring infectious cysts (sarcocysts). The sarcocysts rupture in the small intestine and release bradyzoites, which infect intestinal epithelial cells. The bradyzoites differentiate into microgametes and macrogametes, which initiate sexual reproduction eventually resulting in the formation of oocysts. Oocysts sporulate in the lumen of the intestine; mature oocysts are thin-walled and possess two sporocysts, each with four sporozoites. Both intact oocysts and individual sporocysts liberated from ruptured oocysts are shed into the environment in the feces. Cattle and pigs become infected after eating sporocysts and oocysts while grazing on plants contaminated with human feces. Sporozoites liberated in the intestines of the intermediate host infect the endothelial cells of blood vessels. The parasites undergo two generations of schizogony. Merozoites from the second-generation schizonts invade muscle tissue and form sarcocysts containing many infectious bradyzoites (Fayer et al., 2015).

Pathogenesis, clinical presentation, and treatment

Like infection with the other coccidia, intestinal sarcocystosis results in disruption of the intestinal barrier and malabsorption. Many infected patients are asymptomatic or have only mild symptoms (Fayer, 2004; Fayer et al., 2015). When present, symptoms commonly include present with watery diarrhea, nausea, vomiting and abdominal pain. Occasionally a peripheral eosinophilia may be observed. Symptoms generally appear between 2 days to 2 week following ingestion of tissue sarcocysts in undercooked pork or beef (Fayer, 2004). Symptoms are self-limited in most cases and resolve within 1–2 days; however, infected individuals may shed oocysts and sporocysts in their stool for a year or more. There is no antiparasitic agent for intestinal sarcocystosis with proven efficacy (Fayer, 2004).

Diagnosis

The diagnosis of intestinal sarcocystosis is made by microscopy, primarily examinations of wet mounts of stool. Individual sporocysts will autofluoresce when examined under UV illumination, but the oocyst wall will not (Fayer et al., 2015). Sporocysts can also be visualized in MAF-stained stool specimens (Abou El-Naga and Gaafar, 2014). Oocysts measure 15–19 µm long by 15–20 µm wide; individual sporocysts are ovoid and measure 15–19 µm long by 8–10 µm wide (Ash and Orihel, 2007).

Nematode infections

Ascaris lumbricoides (ascariasis)

Biology and epidemiology

Ascariasis is caused by *Ascaris lumbricoides*, the largest nematode inhabiting the human intestinal tract. *Ascaris lumbricoides* has a nearly worldwide distribution and pigs are a major animal reservoir, especially in industrialized societies. Ascariasis is one of the soil-transmitted helminthiases, and is thus categorized as an NTD by the WHO. Like the other soil-transmitted helminthiases, the prevalence of infection is highest in poor regions of the world without proper sanitation and access to clean water (Kirk et al., 2015; Jourdan et al., 2018; Else et al., 2020). It is estimated there are 760 million human cases worldwide (Betson et al., 2014), with an associated 923,000 years lost due to disability and 511,000 years of life lost in 2016 (WHO, 2020b).

Human infections associated with pigs are often attributed to *A. suum*. There has been an ongoing debate for decades on the relationships between *A. lumbricoides* and *A. suum* and the validity of the latter as a distinct species. In general, morphological, molecular, and ecological data suggests that *A. suum* is synonymous with *A. lumbricoides* (Leles et al., 2012; Liu et al., 2012). While there are genetic differences in worm populations around the world, and that humans and pigs may harbor different genetic populations in endemic areas, it is still unclear whether those differences represent two or more species with a common ancestor, or there were multiple human colonization events from pigs (or vice versa) over time in different geographic areas, or there is a single species with geographic variations, the latter of which becomes more problematic given the global migration of humans and the pigs they bring with them (Betson et al., 2014). From a clinical standpoint, ascariasis is managed the same regardless of the species implicated in human disease.

Fig. 10 Intestinal helminth eggs arranged according to increasing size (unstained). From Pritt B (2014) *Parasitology Benchtop Reference Guide*. Northfield, IL: College of American Pathologists.

Ascaris lumbricoides has a complex life cycle involving a single host. Adults reside in the small intestine of the human host. Female worms may shed fertilized (if mated) or unfertilized eggs into the environment via the feces (Fig. 10). As with other soil-transmitted helminthiases, the eggs are not immediately infectious, and must develop further in the soil. Therefore, there is no person-to-person spread of this parasite. Unfertilized eggs are a dead-end stage, but fertilized eggs will embryonate over 2–4 weeks depending on environmental conditions such as temperature and humidity. Fully embryonated eggs contain an infectious L3 larva. Humans become infected after ingesting fully-embryonated eggs on fomites, food, and water contaminated with soil containing the eggs. The eggs hatch in the upper small intestine. The L3 larvae penetrate the intestinal epithelium and are carried via the bloodstream to the lungs. After about 3 weeks, the L3 larvae penetrate the alveolar walls and ascend the bronchial tree to the epiglottis, where they are coughed up and swallowed. Once back in the small intestine, they molt twice and become adult worms. Adults live for about 1–2 years (Mathison and Pritt, 2018b). Occasionally, adult female worms will migrate to ectopic sites, such as the liver, gall bladder, pancreas, abdominal cavity, kidneys, umbilicus, and pleural cavity. This life-cycle can be interrupted by incorporating good sanitation practices, including proper disposal and treatment of human and pig feces.

Pathogenesis, clinical presentation, and treatment

Like all of the soil-transmitted helminths, the clinical presentation of ascariasis varies by the stage and extent of infection (Jourdan et al., 2018). Light infections are commonly asymptomatic, while heavy infections are associated with significant morbidity, particularly in young children. Death from infection is rare. During the lung migration stage, the larval worms elicit a type-1 hypersensitivity reaction which may produce transient pulmonary symptoms referred to as Loeffler's syndrome. This syndrome generally occurs 9–14 days after and is characterized by dry cough, urticaria, wheezing, and dyspnea. Peripheral eosinophilia (>500 cells per microliter) is common (Akuthota and Weller, 2012). Chest radiograph characteristically show patchy areas of consolidation that may migrate on repeat imaging, and pleural effusion might be noted (Jourdan et al., 2018). Hemoptysis and respiratory distress may occur with heavy infections (Akuthota and Weller, 2012).

The intestinal stage of infection is usually asymptomatic. When present, patients commonly experience abdominal discomfort, anorexia, and altered bowel patterns including diarrhea (Jourdan et al., 2018). Potentially life-threatening complications are due to the large size of the worm; heavy infections, particularly in young children, may present with small bowel obstruction, whereas ectopic migration of one or more adult worms into the biliary tree may result in acute pancreatitis, acute cholecystitis, and hepatic abscess (Jourdan et al., 2018).

Treatment is primarily with the benzimidazole drugs, albendazole or mebendazole (Jourdan et al., 2018). Ivermectin is an alternative therapy. In endemic regions, it common to administer an a benzimidazole drug on a periodic basis to susceptible individuals (e.g. annual school-based deworming programs) to prevent significant morbidity from infection.

Diagnosis

Diagnosis of ascariasis is done by microscopy, including examinations of wet mount of stool to detect eggs, gross morphology of expelled adult worms, and rarely, histopathology for ectopic colonization of adult worms. Larvae can rarely be seen in sputum during the lung migratory stage through sputum microscopy.

Four morphotypes of eggs may be observed in wet mounts of stool, and technologists need to be familiar with all four to ensure a reliable diagnosis. Fertile eggs are 55–75 μm long by 35–50 μm wide and have a thick, multi-layered shell with a bumpy, albuminous layer (mamillated) (Fig. 10). The embryo is at a single-cell stage of development in freshly-processed stool specimens, but will embryonate over time, even in stool some fixatives, such as 10% formalin. Occasionally, the albuminous layer is lacking and the outer shell is smooth (decorticated). Infertile eggs are 85–85 μm long by 43–47 μm wide with internal contents consisting of disorganized granules. As with fertile eggs, infertile eggs may be mamillated or decorticated. Infertile, decorticated eggs can easily be confused for the eggs of other parasites, such as *Fasciola hepatica* and *Fasciolopsis buski*, or plant cells (Ash and Orihel, 2007).

Adult worms expelled in stool are large, smooth, and cream-colored (Fig. 11). Adult females are 20–35 cm long, while males are smaller at 15–31 cm long. Males also tend to have a curved tail. Adults of both sexes have three, fleshy anterior 'lips' (Ash and Orihel, 2007). Adult *A. lumbricoides* needs to be distinguished from L3 larvae of anisakid nematodes, which are generally less than 5 cm long.

Adult worms in ectopic sites may be discovered via radiologic imaging or surgical exploration in acutely symptomatic patients. Alternatively, they may be discovered incidentally in biopsy specimens collected under the suspicion of other etiologies. In the latter situation, the worms are usually dead and calcified or in varying stages of degradation. Sometimes only eggs remain in granulomas. The worms can usually be recognized by the structure of the cuticle, musculature, and intestinal cells; however degrading worms can be very difficult to distinguish from ectopic anisakids. The presence of reproductive structures or eggs would rule-out anisakiasis, as anisakid nematodes do not develop to sexual maturity in the human host (Mathison and Pritt, 2018a). L3 larvae in lung biopsy specimens have several features in common with other ascarid nematodes, including large excretory canals and prominent lateral alae. L3 larvae of *A. lumbricoides* need to be distinguished from visceral larval migrans caused by *Toxocara* spp. (Mathison and Pritt, 2018a).

Capillaria philippinensis (intestinal capillariasis)

Biology and epidemiology

Intestinal capillariasis is caused by the trichuroid nematode *Capillaria philippinensis*. The species was first described from a human patient in the Philippines, but endemic human infection occurs throughout much of Southeast Asia, including China, Korea, Thailand, Laos, Malaysia, and Japan. The disease is established in Egypt as well, and has been identified in a patient from Colombia (Eiras et al., 2018). Additional cases have been reported from the United Kingdom, UAE, Iran, Italy, and Spain (Attia et al., 2012). It is uncertain whether the disease is more widely distributed than historically believed, or if it has been introduced to new areas by human activity or migrating birds.

Fig. 11 Gross morphology of common intestinal helminths arranged according to size (unstained). From Pritt B (2014) *Parasitology Benchtop Reference Guide*. Northfield, IL: College of American Pathologists.

Capillaria philippinensis has a complex two-host life cycle that includes direct and indirect cycles. In nature, the disease is believed to cycle between fish and piscivorous (fish-eating) birds. Humans become infected after eating raw or undercooked fish harboring infectious *C. philippinensis* larvae. The larvae mature to adults in the small intestine. After mating, first-generation females release larvae which infect the host's intestinal epithelium and mature into second-generation adults. After mating, most of these second-generation females release eggs, although some will continue to release larvae, the latter of which results in autoinfection. The autoinfection process results in long-standing infection of the host, which eventually progresses to hyperinfection. Eggs are shed into the environment unembryonated or partially embryonated (Fig. 10). Eggs embryonate in 5–10 days under normal environmental conditions. Fully-embryonated eggs are ingested by fish and hatch in the fish's intestinal tract. The liberated larvae colonize the tissue of the fish and remain there until eaten by a suitable definitive host (Cross, 1992).

Pathogenesis, clinical presentation, and treatment

Intestinal capillariasis is a serious, progressive infection, which may lead to death if untreated due to ongoing destruction and disruption of the intestinal mucosa (Cross, 1992). Patients most commonly present with chronic watery diarrhea, abdominal pain, vomiting, anorexia, malaise, and weight loss. Symptoms progress over time due to ongoing autoinfection. Eventual hyperinfection results in severe weight loss, malabsorption, protein-losing enteropathy, and electrolyte imbalances (Cross, 1992; Limsrivilai et al., 2014). Treatment is albendazole or mebendazole (Medical Letter, 2013).

Diagnosis

Intestinal capillariasis is diagnosed by microscopy, including wet mount examinations of stool and histopathology of intestinal biopsy specimens.

Eggs of *C. philippinensis* can be detected in wet mounts of stool, and in patients with heavy worm burdens, larvae and occasionally adult worms can also be detected. Eggs are 36–45 µm long by 21 µm wide and have a thick striated shell and inconspicuous polar protuberances on each end (Fig. 10). The eggs are often slightly indented medially giving them a peanut-shaped appearance (Ash and Orihel, 2007). Larvae are 130–300 µm in length and possess stichocytes along the esophagus (Cross, 1992).

Biopsy specimens of the small intestine may reveal adults, larvae, and eggs. Adults and larvae have typical trichuroid morphologic features, such as stichocytes and bacillary bands, and need to be distinguished from *Trichuris trichiura* and *Trichinella* spp. Adults of *T. trichiura* are larger than those of *C. philippinensis* and have a marked difference in the diameter of anterior and posterior regions of the body. Adults of *Trichinella* are smaller than those of *C. philippinensis* and do not produce eggs in tissue or stool. Because of a similar autoinfective cycle, *C. philippinensis* may resemble *Strongyloides stercoralis*, the latter of which lacks features common to trichuroid nematodes, such as stichocytes and bacillary bands (Mathison and Pritt, 2018a).

***Necator americanus* and *Ancylostoma* species (intestinal hookworm infection)**

Biology and epidemiology

Most cases of intestinal hookworm infection are caused by one of three species: *Necator americanus*, *Ancylostoma duodenale*, and *A. ceylanicum*. Classified as a Neglected Tropical Disease (NTD) along with other soil-transmitted helminths, it is estimated there are over 439 million hookworm infections worldwide (Hotez et al., 2014). The WHO estimates that hookworm infections were responsible for 1,682,000 disability-adjusted life years in 2016. *Necator americanus* and *A. duodenale* have a nearly worldwide distribution in the tropics and subtropics (WHO, 2020a). Major areas of endemicity for *N. americanus* include southern and southwestern China, southern India, Southeast Asia, sub-Saharan Africa, and Latin America. Coastal areas of these regions appear to have increased transmission. Major areas of endemicity for *A. duodenale* include northern regions of China and India, Egypt, northern Australia, and Latin America (Brooker et al., 2004). Hookworm infection has been largely eradicated from the United States, but sporadic cases do still occur, especially in impoverished areas of the South. Mixed infections of *N. americanus* and *A. duodenale* are not uncommon where the two species overlap (Brooker et al., 2004). *Ancylostoma ceylanicum*, a common parasite of dogs and cats in Asia which historically been regarded as an uncommon zoonotic parasite in humans, is now believed to be one of the leading causes of human hookworm infection in Southeast Asia (Traub, 2013). *Necator gorillae* causes uncommon zoonotic infection in western Africa (Kalousova et al., 2016).

Hookworms have a complex one-host life cycle. Adults reside in the small intestine. Mated females lay unembryonated or partially-embryonated eggs into the environment in the feces. Under optimal conditions in soil, eggs embryonate within 24–48 h and hatch, releasing first-instar (L1) larvae. The L1 larvae molt twice and become infectious L3 larvae in the soil. Humans are infected when L3 larvae penetrate intact skin when walking barefoot or in sandals over contaminated soil; *A. duodenale* can also cause infection from ingestion of L3 larvae on food or fomites contaminated with soil. The larvae are carried via the bloodstream to the right side of the heart and then to pulmonary vessels. The larvae rupture pulmonary capillaries and enter the lung parenchyma, ascend the bronchial tree to the epiglottis, and then are coughed up and swallowed. Once in the small intestine, they molt twice to become adults. The adult worms attach to the intestinal mucosa using specialized mouthparts and feed on the blood of the host (Figs. 12 and 13). It takes approximately 6–8 weeks from the time L3 larvae penetrate the skin to sexual maturity of the adults (Hotez et al., 2004).

Fig. 12 Mouthparts of adult hookworms used to attach to the small intestine and feed from blood vessels within the mucosa. *Ancylostoma* species have “teeth” (left), while *Necator americanus* has cutting plates (right). From Mathison BA and Pritt BS (2018) Chapter 5: Parasitic diseases. In: Atlas of Fundamental Infectious Diseases Histopathology: A Guide for Daily Practice. Pritt BS (ed.). Northfield, IL: College of American Pathologists.

Fig. 13 Two adult hookworms embedded in the intestinal mucosa. Courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

Pathogenesis, clinical presentation, and treatment

Hookworm infections are commonly asymptomatic (Jourdan et al., 2018). When present, symptoms vary by the stage of infection and worm burden. Patients may initially present with a pruritic rash (i.e., “ground itch”) at the site of skin penetration by the infective larvae. Later, Loeffler’s syndrome may rarely occur when larvae migrate through the lungs. Finally, the intestinal stage of infection may be accompanied with abdominal pain, diarrhea, blood in the stool (microscopic, or rarely macroscopic), and anemia. Patients with a heavy worm burden may experience severe anemia due to ongoing blood loss from the feeding adult worms. Young children and pregnant women are particularly at risk for poor outcomes due to anemia, hypoalbuminemia, and malnutrition (Jourdan et al., 2018). Treatment is albendazole or mebendazole (Medical Letter, 2013, Jourdan et al., 2018). In endemic regions, it is common to administer a benzimidazole drug on a periodic basis to susceptible individuals (e.g. annual school-based deworming programs) to prevent significant morbidity from infection. Patients should also be educated on preventative measures such as adequate sanitation and regular use of footwear (Jourdan et al., 2018).

Diagnosis

Intestinal hookworm infection is diagnosed primarily by the detection of eggs, and less-commonly L1 larvae, in wet mount examinations of stool. Adults may be removed by endoscopy and identified grossly by the structures of their mouthparts. Routine molecular diagnosis for intestinal helminths is still in its infancy; however, regional laboratories have developed LDTs for the detection of hookworm.

Female hookworms have a relatively high fecundity, and finding eggs in a positive stool specimen does not usually present with any problems if the specimen is processed properly. Eggs of *N. americanus* are 60–75 μm long by 36–40 μm wide, have a thin, colorless shell, and are in an early cleavage stage in freshly-processed feces. The eggs of *Ancylostoma* spp. are slightly smaller, at

55–65 μm long by 36–40 μm wide. Due to these inappreciable differences in size, it is essentially impossible to morphologically separate the eggs of *N. americanus* and *Ancylostoma* spp. in stool specimens. When hookworm eggs are detected in wet mounts of stool, it is common practice to report them generically as “hookworm eggs” and not at the genus or species level (Ash and Orihel, 2007). Identification to the genus or species level is not needed for clinical management of patients. Hookworm eggs are also very similar to the eggs of *Trichostrongylus* spp. (Fig. 10; see below).

If there is a delay in processing stool specimens, the eggs may embryonate and hatch and L1 larvae may be present in O&P exams. The L1 larvae of hookworm need to be distinguished from L1 larvae of *Strongyloides stercoralis*, which are also detected in stool. The L1 larvae of hookworm are 250–350 μm long, have a long buccal canal, and an inconspicuous genital primordium. In contrast, the L1 larvae of *S. stercoralis* 180–380 μm long and possess a short buccal canal and a prominent genital primordium (Ash and Orihel, 2007).

Adult males of *N. americanus* measure 5–9 mm long; females are slightly larger at 9–11 mm long (Fig. 11). Adults of both sexes have a buccal capsule (mouth) containing prominent cutting plates. Adults of *Ancylostoma* spp. are similar in size; males measure 8–11 mm long and females measure 10–13 mm long. Instead of cutting plates in the buccal capsule, adults of *Ancylostoma* have two sets of teeth (Fig. 12) (Ash and Orihel, 2007). Adults of *A. duodenale* and *A. ceylanicum* can be separated by the form of the teeth. In *A. ceylanicum*, the outer (lower) teeth are much larger than the inner (upper) teeth, whereas the two pairs of teeth in *A. duodenale* are similar in size and shape (Yoshikawa et al., 2018).

Trichostrongylus species (trichostrongylosis)

Trichostrongylosis is a zoonotic helminth infection caused by nematodes in the genus *Trichostrongylus*, including *T. orientalis*, *T. columbiformis*, and *T. axei*. Normally a parasite of herbivorous mammals, humans can become infected after the ingestion of infectious L3 larvae on contaminated produce. Human infection is not common, but sporadic cases have reported from many countries, including Laos, Thailand, China, South Korea, Iran, Australia, and the United States (Sato et al., 2011).

The clinical picture of trichostrongylosis is not well described. Most patients are asymptomatic, but some may present with diarrhea, abdominal pain, anorexia, pulmonary symptoms, and eosinophilia. Cutaneous manifestations are rare (Ghanbarzadeh et al., 2019). Treatment options for trichostrongylosis include albendazole, mebendazole, and pyrantel pamoate (Medical Letter, 2013).

Trichostrongylosis is diagnosed by the detection of eggs in wet mount examinations of stool (Sato et al., 2011). Eggs of *Trichostrongylus* are morphologically very similar to hookworm eggs and the disease may be under-reported in endemic areas. Eggs of *Trichostrongylus* spp. tend to be slightly larger, measuring 75–95 μm long by 40–50 μm wide (Fig. 10). The eggs taper noticeably to one end and the embryo is usually in an advanced stage of cleavage when shed in feces (Ash and Orihel, 2007).

Strongyloides stercoralis (strongyloidiasis)

Biology and epidemiology

Most cases of strongyloidiasis are caused by *Strongyloides stercoralis*, a nematode with a nearly cosmopolitan distribution. As the molecular epidemiology of the disease becomes better understood, it is apparent that some human infections in Africa, Southeast Asia, New Guinea, and Australia are attributed to *S. fuelleborni*, a parasite of non-human primates in Africa and Asia (Barratt et al., 2019). Classified as an NTD, the global burden of *S. stercoralis* is difficult to calculate due to poor or nonexistent reporting in some areas and the low sensitivity of traditional diagnostic assays, such as stool exam. It is believed there are anywhere from 3 to 100 million people infected worldwide, although these numbers are not believed to be close to the true prevalence of the disease globally. Major areas of soil-borne transmission are Latin America, sub-Saharan Africa, and Southeast Asia. In developed countries or areas where fecal contamination of soil is rare, major risk factors include HIV infection, HTLV-1 infection, alcoholism, organ transplantation, and patients undergoing corticosteroid therapy (Schar et al., 2013).

Strongyloides stercoralis has a complex life cycle including both parasitic and free-living stages. Adult females (only) reside in the epithelium of the small intestine. They reproduce parthenogenetically (without fertilization by a male) and shed embryonated eggs containing an L1 (rhabditiform) larva into the lumen of the intestine. The eggs hatch in the small intestine and the L1 larvae take one of three pathways, two environmental and one internal. L1 larvae shed in the feces take one of two pathways in soil. They either molt twice and become infectious L3 (filariform) larvae that infect a new host, or they mature all the way to adults. In the latter, both free-living adult males and females occur. They mate and the females produce embryonated eggs containing L1 larvae. When the eggs hatch, the larvae molt twice to become infectious L3 larvae. There is only one generation produced in the environment; perpetuation of the free-living cycle requires continued contamination of the environment with human feces. Regardless of the pathway to the production of L3 larvae, human infection occurs when L3 larvae penetrate intact skin when people walk barefoot or in sandals on contaminated soil. Historically, it was believed that the larvae were carried via the bloodstream to the heart and then the lungs, before being coughed up and settling in the small intestine, much like hookworm. It is now believed that migration to the small intestine is random through tissues in the body. Once in the small intestine, the L3 larvae molt twice to become parthenogenetic females. The third pathway the L1 larvae can take is autoinfection. The L1 larvae become L3 larvae while still in the intestinal tract. These L3 larvae penetrate the intestinal epithelium and mature to adult females, which continue the cycle. Autoinfection can lead to chronic disease lasting decades, with the infection largely being kept in check by the host's immune system. If a patient becomes immunocompromised, (e.g. immunosuppression prior to organ transplantation, corticosteroid use), the L3 larvae can disseminate in large numbers to other parts of the body, including the kidneys, skin, and lungs, leading to life-threatening hyperinfection (Page et al., 2018).

Pathogenesis, clinical presentation, and treatment

Infection is usually asymptomatic in immunocompetent, otherwise healthy individuals (Jourdan et al., 2018). L3 larval migration through various organs may result in localized symptoms; a Loeffler's like syndrome may occur with the initial pulmonary migration, whereas a serpiginous urticarial rash called larva currens may be seen during chronic infection. A skin rash ("ground itch") may also be noted at the initial site of skin penetration, like what is seen with hookworm. Immunocompromised individuals are at risk of hyperinfection syndrome, where the host immune response is no longer able to keep the autoinfection cycle under control. In this case, the large migration of L3 larvae from the intestinal tract to the lungs and other organs can result in recurrent sepsis and/or meningitis with bowel bacterial flora, mucosal and pulmonary bleeding, and respiratory collapse (Jourdan et al., 2018). Patients are risk for hyperinfection syndrome include those receiving chemotherapy for hematologic malignancies, patients with human T-cell lymphotropic virus type 1 (HTLV-1) infection, and patients with hypogammaglobinemia (Jourdan et al., 2018). Unlike the other soil-transmitted nematodes, the first line anti-helminthic drug is ivermectin (Medical Letter, 2013).

Diagnosis

The diagnosis of strongyloidiasis is challenging. Historically, strongyloidiasis was diagnosed by the detection of L1 larvae in wet mounts of stool. Unfortunately, this method has low sensitivity. Detection of *S. stercoralis* in stool can be enhanced by methods such as the Baermann technique, or preferably, the stool agar culture (De Kaminsky, 1993; Salazar et al., 1995). Disseminated disease and hyperinfection can be diagnosed by the finding of L3 larvae in respiratory specimens and other body fluids or by the histopathologic examination of biopsy specimens. Adult females, larvae, and eggs may be detected in biopsy specimens of the small intestine. Diagnosis of chronic strongyloidiasis and the screening of patients prior to organ transplantation or immunosuppression for malignancy is performed by antibody detection, although available assays have varying degrees of sensitivity and specificity. NAATs are not widely used for routine clinical diagnosis, but large reference labs and labs in endemic areas may employ them as LTDs.

Microscopy

Although insensitive, the "gold standard" for the diagnosis of strongyloidiasis is the detection of L1 larvae in stool by the O&P examination. Due to the low sensitivity of morphologic analysis, upwards of seven serial stool specimens should be examined (Siddiqui and Berk, 2001). Detection in stool can be enhanced by the Baermann technique. For this method, stool is placed in a coarse mesh screen and placed suspended in a funnel that is filled with warm water. The bottom of the funnel is connected to a clamped tube. L1 larvae in the stool develop to L3 larvae and enter the water, which is drained into the tube, centrifuged, and examined by microscopy. Laboratorians performing this technique must be careful, as live L3 larvae are infectious if they come in contact with skin (Requena-Mendez et al., 2013). The string test (see under *Giardia duodenalis*, above) can also enhance diagnosis.

L1 larvae in stool are 180–380 μm long by 14–20 μm wide. They possess a short buccal canal and a prominent genital primordium (Fig. 14). L3 larvae observed in stool exams (especially if there was a delay in processing), retrieved from a Baermann funnel, or in extraintestinal specimens such as bronchial washings and BALs are longer, measuring upwards of 600 μm in length. They have a notched tail and there is a 1:1 ratio of esophagus to intestine. Unlike with L1 larvae, the form of the buccal canal and genital primordium in the L3 larvae are not diagnostically important (Ash and Orihel, 2007).

Adult females in biopsy specimens of the small intestine are small, measuring 30–40 μm in diameter. They can usually be recognized by their prominent alimentary canal and paired uterine tubes that usually contain eggs in various stages of development. L3 larvae in cross section will reveal tiny, paired lateral alae (Mathison and Pritt, 2018a).

Fig. 14 *Strongyloides stercoralis* L1 (rhabditiform) larva in stool (wet mount, 400 $\times$).

Stool culture

Probably the most sensitive test for diagnosing strongyloidiasis is the agar plate culture (APC) method. For this method, fresh stool is placed in a petri dish containing agar culture medium, such as blood agar. After L1 larvae in the stool become L3 larvae, they migrate over the surface area of the agar plate, carrying bacteria with them. Bacterial growth in the tracks becomes visible to the unaided eye (Fig. 15). Strongyloidiasis should be strongly suspected when these tracks are seen, however the specimen should be confirmed by microscopy, as hookworm L3 larvae will make visible tracks as well. While more sensitive, the APC method has its disadvantages, most notably being time consuming and presenting a safety risk to laboratorians performing the assay (Requena-Mendez et al., 2013).

Antibody detection

Anybody detection is used primarily for diagnosing chronic strongyloidiasis and for screening organ transplant recipients prior to immunosuppressive therapy. Several different serologic methods have been developed for the diagnosis of strongyloidiasis. Unfortunately, few have a sensitivity greater than 80% on average, and that can decrease in immunocompromised patients. Also, several of these assays cross-react with other nematode infections. In patients where the predictive positive value is high, EIA assays are more sensitive than IFA. One commercial assay, the IVD *Strongyloides* Serum Antibody Detection Microwell ELISA kit (IVD Research, Inc., Carlsbad, California) has a sensitivity of 73–100% and a specificity of 29–93%, but may exhibit lower sensitivity in immunocompromised patients. It also exhibits high cross reactivity to other nematode infections. The *Strongyloides* ELISA produced by Bordier Infinity Products (Crissier, Switzerland) was developed using antigens to *S. ratti* and exhibits a sensitivity of 88% and a specificity of 94% in patients without other helminth infections. The specificity drops to 77% in patients with other helminth infections, however (Requena-Mendez et al., 2013). Western blots show promise of high sensitivity, but also struggle with cross reactivity in patients with other helminth infections and are not widely available outside of specialized reference labs (Requena-Mendez et al., 2013). A luciferase immunoprecipitation system (LIPS) using recombinant *Strongyloides* antigen shows high sensitivity (97%) and specificity (100%) with no cross reaction with filarial infections. Unfortunately, the assay is not available outside of specialized reference laboratories (Bisoffi et al., 2014; Requena-Mendez et al., 2013).

Antibody detection can be an important part of the algorithm when screening pre-transplant recipients for strongyloidiasis. Normally potential transplant recipients are screened by EIA. However, given the lower sensitivity of this assay, it is recommended that pre-transplant patients with a negative EIA result but high epidemiological risk for strongyloidiasis or unexplained eosinophilia still get treated prior to immunosuppressive therapy (Mobley et al., 2017; Roxby et al., 2009).

NAATs

Like with many helminth infections, molecular diagnosis of *S. stercoralis* is still not routinely available outside of specialized reference labs. Currently, it is generally not believed that PCR is adequate for screening for *S. stercoralis* as it does not provide sensitivity superior to traditional methods, such as the Baermann technique (Buonfrate et al., 2018). Loop-mediated isothermal amplification (LAMP) assays has been developed which show promise, but are currently not superior to conventional or real-time PCR assays (Watts et al., 2019).

Fig. 15 Bacterial growth along serpiginous *Strongyloides stercoralis* tracks (arrows) on sheep blood agar. This was an incidental finding on a stool bacterial culture.

Trichinella* species (trichinellosis, trichinosis)*Biology and epidemiology**

Trichinellosis (trichinosis) is a zoonotic disease caused by trichuroid nematodes in the genus *Trichinella*. Depending on the taxonomy applied, up to eight species and genotypes have been implicated in human infection. These species, along with their geographic distribution and common sources of human infection, include *T. spiralis* (cosmopolitan; domestic and wild pigs, horses), *T. nativa* (Arctic regions of North America and Eurasia; bears, walrus), *T. britovi* (North America; wild and domestic pigs, wild carnivores, horses), *T. murrelli* (North America; bears, horses), *T. nelsoni* (sub-Saharan Africa; bush pigs and warthogs), *T. pseudospiralis* (cosmopolitan; domestic and wild pigs), *T. papuae* (Papua New Guinea, Thailand; wild pigs), and *Trichinella* genotype T6 (North America; bear, mountain lion) (Gottstein et al., 2009).

Human infection is usually described as originating from a domestic cycle or sylvatic cycle. In the domestic cycle, *Trichinella* cycles between domestic animals, such as pigs and horses, and anthropophilic rodents. Due to improvements in animal husbandry practices in developed countries, the domestic cycle is significantly less common, and is usually seen in home-raised livestock or small community farms rather than large commercial meat producers. In the sylvatic cycle, the worms cycle between wild carnivorous and omnivorous animals, and human infection usually occurs from the ingestion of wild game, such as wild pigs and bears (Mathison and Pritt, 2018b).

Trichinella species have a complex life cycle in which a host serves as a definitive host, intermediate host, and possibly a dead-end host. Infection occurs when L1 larvae are ingested in the undercooked muscle of an infected animal. The larvae are released in the stomach of the host and travel to the small intestine where they penetrate the intestinal epithelium. The L1 larvae molt four times within 48 h to become sexually-mature male and female worms. Mated females release L1 larvae into the lymphatics and the larvae migrate to striated muscle. They penetrate the muscle cells and develop to an infectious form contained within a “nurse cell,” the host muscle cell programmed by the parasite to sustain its existence for a period of time. Of the species that have been implicated in human disease, all except *T. pseudospiralis* and *T. papuae* are encapsulated in the nurse cell. The larvae remain dormant in the nurse cells until the muscle of the host is consumed by a new host. If the host is not eaten, the larvae will eventually calcify and die. Continuous cycles of carnivory are needed to keep the life cycle going. Humans are typically dead-end hosts for *Trichinella* spp. (Gottstein et al., 2009).

Pathogenesis, clinical presentation, and treatment

There are two phases of human infection: the intestinal phase and invasive phase (Gottstein et al., 2009). Some scientists break the invasive phase into 2 parts: the parenteral (blood stream) phase and the muscle encystment phase. Any stage may be asymptomatic, but patients are more likely to present with symptoms when more than a few hundred larvae are released by the adult worms in the intestinal tract. Thus, the initial burden of ingested larvae and the percentage that develop into adult worms are important drivers of clinical manifestations. The infecting *Trichinella* species may also impact extent and duration of observed symptomatology (Gottstein et al., 2009).

The intestinal (enteral) phase is caused the presence of the adult worms and the newly-released larvae in the intestinal mucosa, and is characterized by self-limited abdominal pain and diarrhea appearing approximately 2 days after ingestion. The invasive (parenteral and encystment) phase begins approximately 1 week after infection when the larvae enter the blood stream. Their presence invokes a host inflammatory response characterized by eosinophilia and a Th2-oriented cytokine profile (Gottstein et al., 2009), including production of IgE. Mast cells, monocytes and lymphocytes are also recruited. The resultant release of serotonin, histamine, prostaglandins, and bradykinin causes fever, edema, vasculitis and intravascular thrombosis – hallmarks of acute-stage systemic disease. Characteristic findings include conjunctivitis, periorbital edema and subungual (“splinter”) hemorrhages (Fig. 16). As the larvae penetrate skeletal muscle, muscle pain and elevated serum muscle enzymes (creatine phosphokinase and

Fig. 16 Characteristic features of acute disseminated trichinosis: periorbital swelling and conjunctivitis (left) and splinter hemorrhages of the nail beds (right). These clinical manifestations are due to the host's immune response to the migrating *Trichinella* sp. larvae. Courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

lactate dehydrogenase) are observed. These symptoms generally last for 1–3 weeks and may be associated with life-threatening myocarditis, encephalitis, and thromboembolic disease. After 3 weeks, patients enter the encystment (chronic) stage of systemic trichinellosis, which may be characterized by encephalitis and cortical infarcts, as well as secondary bacterial pneumonia and sepsis. Of note, patients may experience persistent numbness, decreased muscle strength, conjunctivitis, and excessive sweating for months to years after infection (Gottstein et al., 2009). Treatment is with albendazole or mebendazole, in conjunction with glucocorticosteroids to decrease the damage caused by the host immune response. Additional treatment may be required for pain management and correction of fluid and electrolyte imbalances (Gottstein et al., 2009; Medical Letter, 2013).

Diagnosis

The diagnosis of trichinellosis is made by considering the patient's clinical presentation in combination with a thorough epidemiological investigation, and confirmed by laboratory testing. Antibody detection is the gold standard for laboratory diagnosis of trichinellosis. Larvae can also be detected in partially-digested muscle specimens or by histopathologic examination, although biopsies are rarely collected when trichinellosis is suspected. Molecular assays are not widely used for primary diagnosis, but may be used for epidemiologic investigations in determining the source of infection.

Microscopy

L1 larvae of *Trichinella* may be detected in muscle biopsies, either by pepsin-digestion methods or histopathology. The pepsin-digestion method involves placing a small sample of muscle in a solution of 0.5% pepsin and 0.7% hydrochloric acid and incubating at 37 °C in a closed petri dish for a minimum of 4 h. After incubation, the partially-digested muscle can be pressed between two glass microscope slides and examined under low magnification for coiled and, for most species, encapsulated larvae (Ash and Orihel, 1987). Larvae in muscle biopsies processed for histopathology are coiled and, with the exception of *T. pseudospiralis* and *T. papuae*, contained within a hyaline cyst. Larvae of *Trichinella* possess typical trichuroid features such as stichocytes and bacillary bands (Mathison and Pritt, 2018a). The presence of a coiled, encapsulated nematode in muscle is pathognomonic for trichinellosis (Fig. 17).

Antibody detection

The primary serologic assay for the clinical diagnosis of trichinellosis is EIA targeting IgG antibodies, which are usually present 12–60 days post infection. Depending on the assay, IgE, IgA, and IgM may be detected, but do not provide diagnostic relevance for routine clinical diagnosis. IFA is also available for diagnosing trichinellosis, but it is more time consuming and expensive than EIA (Gottstein et al., 2009).

NAATs

Molecular diagnosis of trichinellosis is primarily performed on meat samples in order to get a species-level identification for epidemiological purposes. Typically, PCR is used targeting the ITS1 and ITS2 subregions and the expansion segment V region of the rRNA repeat (Gottstein et al., 2009). Recently, a multiplex qPCR assay was developed for the detection and identification of encapsulated North American *Trichinella* species in both human clinical specimens and meat samples (Almeida et al., 2018). Species and genotype data are collected and archived by the International Trichinella Reference Centre (<http://www.iss.it/site/Trichinella/index.asp>).

Fig. 17 *Trichinella* sp. larva within a host muscle (“nurse”) cell (hematoxylin and eosin stained, 400 ×). The coiled larva is seen in both longitudinal and cross sections in this histologic preparation. Note the stichosome (arrows) and thick outer capsule (arrow head). Northfield, IL: College of American Pathologists.

Angiostrongylus costaricensis (human abdominal angiostrongyliasis)

Human abdominal angiostrongyliasis (HAA) is caused by *Angiostrongylus costaricensis*, a zoonotic nematode that occurs throughout much of Latin America, from southern Texas in the US to South America. Most human cases have been reported Costa Rica, with additional cases from Honduras, Venezuela, Brazil, Panama, and several Caribbean islands (Romero-Alegria et al., 2014). *Angiostrongylus costaricensis* has a complex two-host life cycle. The natural definitive hosts are rodents, primarily members of the family Cricetidae (New World rats and mice), Heteromyidae (kangaroo rats), and Muridae (Old World rats and mice) (Dard et al., 2018). Adults reside in the ileocecal mesenteric arteries of the definitive host. Eggs hatch in the ileum and L1 larvae are shed into the environment via the feces. L1 larvae are ingested by an appropriate intermediate host, which are terrestrial mollusks, including snails, slugs, and semi-slugs. In the mollusk host, the parasite molts twice to become in infectious L3 larva. A new rodent host becomes infected after eating infected mollusks, and the L3 larvae molt twice to become adults in the mesenteric vessels. Humans also become infected after the ingestion of raw or undercooked mollusks or parts thereof on contaminated produce. The parasite behaves similarly in the human host as it does the rodent host (Ortega and Sterling, 2017).

The hallmark clinical presentation of HAA is eosinophilic enteritis. Patients may present with fever, anorexia, vomiting, and pain in the right iliac fossa, right flank, or upper right quadrant, and symptoms may mimic appendicitis. Pathologically, there are three principle findings. First is a heavy infiltration of eosinophils in the intestinal wall, especially in the intestinal mucosa. Next is a granulomatous reaction surrounding enteric vessels consisting primarily of giant cells, epithelioid cells, and eosinophils. Third is eosinophilic vasculitis of the arteries, veins, capillaries, and lymphatics, often with accompanying epithelial ulceration (Ortega and Sterling, 2017; Mathison and Pritt, 2018a). There is no proven anthelmintic treatment for HAA.

The diagnosis of HAA is made by the finding of worms and their eggs in biopsy specimens processed for histopathology. Adult worms are usually localized in blood vessels while embryonated and unembryonated eggs are usually found in associated tissues. Adults are characterized by coelomyarian/polymyarian musculature, large, nucleated intestinal cells, and conspicuous dome-shaped lateral chords. Gravid females have paired uterine tubes that usually contain eggs in various stages of maturation. Eggs are usually thin-shelled and measure 68–74 µm long by 46–48 µm wide (Mathison and Pritt, 2018a).

Trematode infections

Several trematodes (i.e., flukes) can infect the human gastrointestinal tract, including those that infect the intestine, biliary tree, and mesenteric blood vessels. All but the schistosomes (see below) are acquired through ingestion of raw or undercooked food containing the infective form of the parasite (metacercariae) for humans. These food-borne trematodiasis are classified as NTD by the WHO, and are estimated to cause 2 million life years lost to death and disability each year (WHO, 2020a). As zoonotic infections, they also have a significant economic impact due to losses in aquaculture and livestock.

The food-borne trematodes have a complex life cycle that includes two non-human intermediate hosts, the first of which is always a freshwater snail, and a definitive host (e.g., humans and other animals). Transmission to humans is largely dependent on culinary practices and access to fresh water, and thus infections are often limited to specific geographic regions of endemic countries. The extent of symptomatology varies with the worm burden, and many light infections are asymptomatic. The anti-helminthic drug of choice is praziquantel for all trematodiasis except for *Fasciola hepatica* infection (fascioliasis).

Fasciolopsis buski (fasciolopsiasis)

Biology and epidemiology

Frequently known as the “giant intestinal fluke,” *Fasciolopsis buski* is a large intestinal trematode endemic to freshwater habitats in Southeast Asia. Natural reservoirs for human infection are primarily pigs, but also non-human primates, dogs, and rabbits (Ma et al., 2017). Hot spots of human infection include China, Nepal, Cambodia, India, Laos, Myanmar, Taiwan, Thailand, and Vietnam (Sah et al., 2019).

Like all trematodes, *F. buski* has a complex life cycle involving multiple hosts. Adult flukes reside in the small intestine of the definitive host (Fig. 18). Unembryonated eggs are shed into the environment via the feces. Eggs in freshwater develop over a period of 3–7 weeks, resulting in the formation of a first stage larva (miracidium) within each egg. The eggs hatch and the miracidia infect an appropriate snail host, which for *F. buski* are primarily members of the genera *Segmentina* and *Hippeutis*. Within the snail, the parasite undergoes several cycles of asexual reproduction, resulting in the formation of cercariae. The cercariae leave the snail host and encyst on freshwater vegetation as metacercariae. The definitive host, including humans, becomes infected after eating uncooked vegetation harboring metacercariae or from drinking water contaminated with liberated metacercariae (Sah et al., 2019).

Pathogenesis, clinical presentation, and treatment

As with all of the intestinal flukes, the clinical presentation varies by the extent of infection. The adult flukes attach to the intestinal wall with their oral and ventral suckers, causing localized hemorrhage, inflammation and ulceration. The flukes may also interfere with absorption, and their large size can cause transient small bowel obstruction. Infection is frequently asymptomatic in patients with a low worm burden (Maguire, 2020), whereas heavy infections (e.g., >100 worms) are more likely to be clinically significant. Common symptoms include epigastric pain, nausea, and diarrhea (Sah et al., 2019). Edema of the extremities and face may be seen in heavy infections due to protein loss from malabsorption, protein-losing enteropathy and/or a hypersensitivity reaction to worm metabolites (Maguire, 2020). Eosinophilia and anemia are most pronounced in heavy infections, but may be seen in light infections as well. Treatment is with praziquantel (Medical Letter, 2013).

Fig. 18 *Fasciolopsis buski* adult flukes seen in the large intestine during colonoscopy. The smaller flukes are *Gastrodiscoides hominis*. Courtesy of Dr. Sandeep T.

Diagnosis

Fasciolopsiasis is diagnosed by the finding of eggs in wet mounts of stool (Fig. 10) or the gross examination of adult flukes removed by endoscopy (Figs. 18 and 19). In heavy infections, flukes may also inhabit the large intestine.

Eggs of *F. buski* are 130–150 μm long by 63–90 μm wide, have a small, inconspicuous operculum, and are unembryonated when shed in stool (Fig. 10). The eggs are morphologically nearly indistinguishable from those of *Fasciola hepatica* and it is common for laboratories to slash call the two species when reporting results (e.g. *Fasciola hepatica*/*Fasciolopsis buski* eggs). The eggs of *F. buski* are also very similar to other large intestinal flukes, such as *Gastrodiscoides hominis* and *Echinostoma* spp. A definitive identification can be challenging in endemic areas where multiple species coexist.

F. buski is the largest of the intestinal flukes. Adults removed by endoscopy are large, flat flukes, measuring 20–75 mm long by 20 mm wide (Figs. 18 and 19). The adults are similar to those of *F. hepatica*, but the location in the host can be helpful in separating them, as *F. buski* lives in the lumen of the small intestine while *F. hepatica* lives in the bile ducts of the liver. Also, the anterior end of *F. buski* is rounded when the specimen is relaxed, compared with that of *F. hepatica* which has a prominent cephalic cone.

Fig. 19 Two *Fasciolopsis buski* flukes removed from the case shown in Fig. 18. The ventral aspect of the flukes is shown, revealing the acetabulum (ventral sucker; arrows). The mouth and oral sucker are directly anterior to the ventral sucker (arrow head). Courtesy of Dr. Sandeep T.

Heterophyes heterophyes, Metagonimus yokogawai, and other small intestinal trematodes (heterophyiasis, metagonimiasis)

Biology and epidemiology

Nearly 30 species of small trematodes have been reported causing zoonotic intestinal human infections in Asia and other parts of the world. Genera implicated in human disease include *Heterophyes*, *Metagonimus*, *Haplorchis*, *Pygidiopsis*, *Heterophyopsis*, *Stellantchasmus*, *Centrocestus*, *Stictodora*, *Acanthotrema*, *Apophallus*, *Procerovum*, *Ascocotyle*, and *Cryptocotyle* (Chai and Jung, 2017). The two species that are most familiar in the clinical realm are *Heterophyes heterophyes* and *Metagonimus yokogawai*. Human infection with *H. heterophyes* occurs in Egypt, Sudan, Palestine, Turkey, India, Japan, and Korea, while human infection with *M. yokogawai* occurs in China, Japan, Korea, Taiwan, Russia, and India (Chai and Jung, 2017).

Regardless of the species implicated in human disease, all of these small intestinal trematodes have a similar multi-host life cycle. Adults reside in the lumen of the small intestine of the definitive host, which in nature are fish-eating mammals and birds. Fully-embryonated eggs are shed into freshwater via the feces. The eggs are ingested by an appropriate snail host and the liberated miracidia penetrate the snail's alimentary canal. The parasite undergoes several cycles of asexual reproduction resulting in the formation of cercariae. The cercariae leave the snail host and infect a fish. In the flesh of the fish, the cercariae encyst as metacercariae, and the definitive host becomes infected after eating raw or undercooked infected fish (Chai and Jung, 2017).

Pathogenesis, clinical presentation, and treatment

As with fasciolopsiasis, the clinical manifestations are dependent on the number of flukes present (Maguire, 2020). The flukes attach to the small intestinal wall, resulting hemorrhage, inflammation and ulceration. Light infections may be asymptomatic, although eosinophilia may be noted. Moderate to heavy infections may result in abdominal pain and diarrhea. The drug of choice is praziquantel (Medical Letter, 2013).

Diagnosis

Regardless of the species, all of these small intestinal trematodes are diagnosed by the detection of eggs in wet mounts of stool. Eggs are often shed in low numbers, and multiple stool specimens may need to be collected and examined for a reliable diagnosis. The eggs of all the species are very similar in size and shape, and in endemic areas where multiple species coexist, a definitive identification may not be possible.

On average, the eggs are 20–30 µm long by 15–17 µm wide and are fully embryonated when shed in feces. The operculum is usually obvious, but the eggs do not have prominent opercular “shoulders” as are seen with some trematodes. Also, the abopercular end does not possess a knob. Because of the morphologic similarity of the eggs of the various species, it is common for laboratories to slash-call names (e.g., *Heterophyes heterophyes*/*Metagonimus yokogawai* eggs). The eggs of small intestinal flukes are also very similar to the eggs of small opisthorchid liver flukes in the genera *Clonorchis* and *Opisthorchis*, although separating the eggs of heterophyid and opisthorchiid trematodes can usually be achieved by the presence of prominent opercular shoulders and an abopercular knob in the latter (Ash and Orihel, 2007).

Miscellaneous intestinal trematodes

Nanophyetus salmincola (nanophyetiasis)

Nanophyetus salmincola is an intestinal fluke of fish-eating mammals and birds in the Pacific Northwest of North America. Humans become infected after the ingestion of raw or undercooked salmonid fish containing infective metacercariae. The clinical picture of nanophyetiasis is not well-described, but patients have presented with generalized gastrointestinal symptoms, such as abdominal pain, diarrhea, nausea, vomiting, increased number of bowel movements, as well as weight-loss, fatigue, and increased eosinophilia (Mathison and Pritt, 2018b). Praziquantel is the drug of choice (Fritzsche et al., 1989). *Nanophyetus salmincola* carries rickettsiae in the genus *Neorickettsia* that can cause a fatal disease in dogs called “salmon poisoning”; humans do not appear to be affected by these bacteria (Greiman et al., 2016).

Nanophyetiasis is diagnosed by the detection of eggs of *N. salmincola* in wet mounts of stool. The eggs are brown, broadly oval, and measure 64–97 µm long by 34–55 µm wide. The operculum is inconspicuous and the abopercular end is noticeably thickened. Eggs of *N. salmincola* need to be distinguished from those of *Paragonimus* spp. and diphylobothriid cestodes (Ash and Orihel, 2007).

Echinostoma spp. and related (echinostomiasis)

Echinostomiasis is a zoonotic disease caused by intestinal trematodes in the family Echinostomatidae (echinostomes). Most cases of human infection have been attributed to members of the genus *Echinostoma*, but several other genera have been implicated in human disease, including *Acanthoparyphium*, *Artyfechinostomum*, *Echinochasmus*, *Euparyphium*, *Himasthla*, *Hypoderaeum*, and *Isthmiophora*. Human cases have been reported nearly worldwide, but endemic foci of human infection are China, India, Indonesia, Korea, Malaysia, the Philippines, and Thailand (Toledo and Esteban, 2016).

Like all trematodes, echinostomes have a complex multi-host life cycle. The natural definitive hosts are aquatic and semi-aquatic mammals and birds. The second intermediate hosts vary greatly depending on the species, and animals implicated in human infection include snails, clams, mussels, freshwater crustaceans, frogs and tadpoles, snakes, and freshwater fish. Water contaminated with metacercariae has also been suggested as a source of human disease (Toledo and Esteban, 2016).

Clinically, echinostomes may cause more severe disease than other intestinal trematodes due to physical damage to the intestinal epithelium caused by the presence of spines surrounding the oral sucker on adult worms. Symptoms include epigastric and abdominal pain, malaise, weight loss, anorexia, nausea, vomiting, and diarrhea. Pathologically, the intestinal epithelium shows mucosal ulceration and erosion, bleeding, and chronic gastritis. Echinostomes have been implicated in adenocarcinoma (Toledo and Esteban, 2016). Praziquantel is the drug of choice (Toledo and Esteban, 2016).

Diagnosis of echinostomiasis is made by the finding of eggs in wet mounts of stool. Eggs are broadly-oval, unembryonated when shed in stool, and have an inconspicuous operculum. There is a broad size range depending on the species, measuring 77–130 μm long by 52–80 μm wide. Because of this broad range, there is considerable overlap with other trematodes, including *Fasciola*, *Gastrophilus*, *Gastrodiscoides*, *Neodiplostomum*, and *Paragonimus*, and a definitive diagnosis may be challenging (Toledo and Esteban, 2016; Ash and Orihel, 2007).

Neodiplostomum seoulense (Neodiplostomum infection)

Neodiplostomum seoulense is a zoonotic intestinal trematode endemic to China and Korea. The natural definitive hosts are rats and the second intermediate hosts are amphibians. Human infection has been attributed to the ingestion of undercooked snakes which serve as paratenic hosts. The clinical picture is not well understood, but patients have presented with acute abdominal pain and fever (Chai and Jung, 2020). Diagnosis is made by the detection of eggs in wet mounts of stool. The eggs are morphologically very similar to those of the echinostomes, measuring 80–102 μm long by 51–63 μm wide, are unembryonated, and possess an inconspicuous operculum (Ash and Orihel, 2007).

Cestode infections

Dibothriocephalus spp., Diphyllbothrium spp., and Adenocephalus spp. (diphyllbothriasis, fish tapeworm disease)

Biology and epidemiology

Diphyllbothriasis is a zoonotic cestode infection. Historically, human infection was attributed to members of the genus *Diphyllbothrium*, until recent morphologic and molecular studies resulted of the splitting of *Diphyllbothrium* into multiple genera. The species implicated in human disease, and their current taxonomic status and broad geographic distributions, are *Adenocephalus pacificus* (southern South America, southern Asia), *Dibothriocephalus latus* (Holarctic), *D. nihonkaiensis* (Asian Pacific, eastern Russia, Pacific Northwest), *D. dendriticus* (Holarctic), *D. dalliae* (Alaska and Siberia), *D. ursi* (North America), *Diphyllbothrium stemmacephalum* (circumpolar), and *D. balaenopterae* (circumpolar). Two additional species implicated in human disease, "*Diphyllbothrium*" *cordatum* and "*D.*" *lanceolatum*, both circumpolar in distribution, are tentatively placed in *Diphyllbothrium* but will probably undergo generic transfer in the future (Kuchta et al., 2015; Waeschenbach et al., 2017).

Like all tapeworms, the diphyllbothriid cestodes have a complex, multi-host life cycle. Adults reside in the small intestine of the definitive host, which in nature are fish-eating mammals and birds. The adults are attached to the intestinal wall by a specialized scolex, while the body (strobila) elongates from the mitotically-active neck region, forming individual units called proglottids. Gravid proglottids, and eggs liberated therefrom, are shed into water (freshwater or marine, depending on the species) via the feces. The eggs are shed unembryonated and after 18–20 days under optimum conditions, release the first instar larva, the coracidium. The coracidium infects a microscopic crustacean and develops into a proceroid larva. The crustacean is eaten by a small fish and develops into a plerocercoid larva (sparganum). A larger, predaceous fish eats the smaller fish and becomes a paratenic host for the plerocercoid larva. The definitive host, including humans, becomes infected after eating undercooked or raw fish harboring plerocercoid larvae. The plerocercoid larva is liberated in the upper small intestine, attaches to the intestinal mucosa via the scolex, and matures to adulthood. Eggs appear in the stool of the definitive host approximately 5–6 weeks post infection (Scholz et al., 2019).

The three species that account for the majority of human infections are *D. latus*, *D. nihonkaiensis*, and *A. pacificus*. Common fish sources of human infection for *D. latus* in North America are pikeperch and walleye and in Europe are perch, pike, and burbot. Common fish sources of human infection for *D. nihonkaiensis* in the North Pacific are salmonid fishes, primarily cherry, pink, chum, and sockeye salmon (Scholz et al., 2009). The epidemiology of *A. pacificus* is less understood. In coastal Peru, infection occurs after the consumption of dishes containing raw seafood, such as ceviche, tiradito, and chingurito, but the host fish is not always known. Plerocercoid larvae of *A. pacificus* have been identified in Eastern Pacific bonito, Atlantic Spanish mackerel, lorna drum, and Peruvian banded croaker, among several other phylogenetically unrelated fish (Kuchta et al., 2015).

Pathogenesis, clinical presentation, and treatment

An estimated 80% of patients with diphyllbothriasis are asymptomatic (Scholz et al., 2009). In these cases, infection may only come to the patient's attention when a large chain of proglottids is passed through the anus. When present, symptoms commonly include abdominal pain, diarrhea, constipation, and fatigue. The latter may be due to a unique feature of some parasites, in which 80% of the host's vitamin B₁₂ intake is absorbed, resulting in megaloblastic anemia (Scholz et al., 2009). Treatment is with praziquantel, with niclosamide as an alternative therapy (Medical Letter, 2013). Vitamin B₁₂ replacement may also be indicated.

Diagnosis

The diagnosis of diphyllbothriasis is made by the detection of eggs in wet mounts of stool (Fig. 10) or the gross examination of adult tapeworms and their proglottids expelled in stool of passed through the anus (Fig. 20). The cestodes causing diphyllbothriasis are the longest to infect humans, reaching lengths of more than 15 m! Chains of proglottids will occasionally break free from the strobila (body) and recovered by the patient.

Fig. 20 Chain of *Diphyllobothrium/Dibothriocephalus* proglottids passed by an otherwise asymptomatic individual. The individual proglottids are wider than they are long, and the dark central uterus is easily appreciated. Courtesy of Phong Duong.

Eggs of all diphylobothriid cestodes are similar in size and shape, and a genus or species-level identification cannot be made by egg morphology. However, a definitive identification is not needed for clinical patient management. The eggs measure 58–75 μm long by 40–50 μm wide, have a moderately thick shell, and are unembryonated when shed in feces (Fig. 10). Unlike other intestinal cestodes of humans, the eggs are operculated, as seen in the eggs of most trematodes. For the most part, the eggs of diphylobothriid cestodes do not overlap in size with those of trematodes that routinely infect humans. Diphylobothriid eggs usually possess a visible abopercular knob, which is also not seen on the eggs of most human trematodes except for those of *Opisthorchis*, *Clonorchis*, and other small liver flukes (Ash and Orihel, 2007).

Proglottids shed in stool are usually in short to long chains (Fig. 20). The mature proglottids are usually broader than long, measuring on average 3.0 mm long by 11.0 mm wide. They possess a characteristic centrally-located rosette uterus, which in a gross specimen may appear as a dark spot in the center of an otherwise pale proglottid. The genital pore is on the mid-ventral surface and the testes are laterally located. The scolex is rarely seen in clinical specimens, as it is small and remains attached to the small intestinal mucosa unless the patient receives antihelminthic therapy. It has dorsal and ventral longitudinal grooves (bothria) used for attachment to the intestinal mucosa of the definitive host (Ash and Orihel, 2007). A genus or species-level identification is possible by analyzing the scolex or the sexual structures of the proglottids, but most clinical laboratories lack the expertise and reference materials to make such an identification.

Taenia saginata, Taenia solium, Taenia sui hominis (intestinal taeniasis)

Biology and epidemiology

Intestinal taeniasis is caused by cestodes in the genus *Taenia*. Three species cause human disease: *T. saginata* (the “beef tapeworm”), *T. solium* (the “pork tapeworm”), and *T. sui hominis* (syn. *T. asiatica*, the “Asian tapeworm”). Taeniasis is classified as an NTD by the WHO (WHO, 2020a). *Taenia saginata* occurs nearly worldwide where raw or undercooked beef is eaten, with a higher prevalence in resource-poor areas of Central Asia, Middle East, and sub-Saharan Africa. *Taenia solium* also has a very wide distribution wherever pigs are raised, but has a higher prevalence in resource-poor areas of Latin America, Africa, India, and Southeast Asia. Neither *T. saginata* nor *T. solium* have a high natural prevalence in North America and Europe where better sanitation and animal husbandry practices occur (Ortega and Sterling, 2017). *Taenia sui hominis*, which historically has been classified as a subspecies of *T. saginata*, is endemic to Southeast Asia with foci of human infection in China, Nepal, Thailand, Sumatra, Indonesia, Taiwan, Korea, and Japan (Ale et al., 2014).

All three species have a complex, two-host life cycle. The definitive hosts are humans, and adult tapeworms reside in the lumen of the small intestine where they are attached to the intestinal wall via a specialized scolex. Proglottids, or eggs liberated therefrom, are shed into the environment in the feces. The eggs are fully-embryonated when passed in feces and contain an infectious first-stage larva called an oncosphere (Fig. 10). Eggs contaminate the environment and are eaten by an appropriate intermediate host (cattle for *T. saginata*; pigs for *T. solium* and *T. sui hominis*) when grazing or foraging. The eggs hatch in the small intestine of the intermediate host, and the oncosphere penetrates the intestinal wall, enters circulation, and is carried to musculature. In the muscle of the intermediate host, the oncosphere develops into the second-stage larva called a cysticercus. After 60–90 days, it reaches its maximum size of approximately 1.0 cm and consists of a protoscolex contained within a thin-walled bladder. A human becomes infected after eating raw or undercooked beef or pork harboring cysticerci. In the small intestine, the liberated cysticercus evaginates and the protoscolex penetrates the intestinal mucosa. The protoscolex matures into the scolex and proglottids start to develop, forming the strobila made up of individual proglottids. Maturation to a sexually-mature adult cestode takes approximately

10–12 weeks. While the adult tapeworms are hermaphroditic and can produce eggs by themselves, the preferred method of reproduction is cross-fertilization between two individual worms in the same host. After approximately 2 months post infection, gravid proglottids break off the strobila and are shed into the environment (Ortega and Sterling, 2017).

Taenia solium is unique among the *Taenia* species as it can cause larval infection (cysticercosis) in the human host after the consumption of eggs in food or fomites contaminated with human feces. Essentially, the human assumes the role of the intermediate host and harbors the cysticerci larvae in musculature and other organs. This is a more dangerous form of infection than taeniasis, as the cysticerci have a predilection for the CNS, resulting in an often debilitating or fatal disease known as neurocysticercosis (Ortega and Sterling, 2017).

Pathogenesis, clinical presentation, and treatment

Patients with intestinal taeniasis are usually asymptomatic (Okello and Thomas, 2017). In this setting, infection may only come to medical attention when the patient passes proglottids through the anus. Freshly-passed proglottids are motile, are may be seen on the surface of stool or found in the undergarments. When present, symptoms commonly include abdominal pain and weight loss. Rarely, proglottids may obstruct the small bowel or biliary tree. Treatment is with praziquantel, with niclosamide as an alternative therapy (Medical Letter, 2013).

Diagnosis

Intestinal taeniasis is diagnosed by the detection of eggs in wet mounts of stool, gross examination of adult tapeworms and proglottids, and coproantigen testing. Molecular testing is only available in specialized reference labs, usually in endemic areas.

Microscopy

The eggs of all three *Taenia* species are morphologically indistinguishable from one another. They are spherical, measure 31–43 μm in diameter, and have a thick, striated shell (Fig. 10). They eggs are fully embryonated and contain an oncosphere with six refractile hooklets. Identification to the species level requires examination of mature proglottids and/or the scolex.

Adults of *Taenia* are large worms, measuring 2–8 m in length (Fig. 21). The scolex of *T. solium* has four suckers and an armed rostellum with two rows of hooklets (usually 26 in total, 13 large and 13 small); the scolex of *T. saginata* also has four suckers but lacks the armed rostellum (snout-like protrusion with a circular row of hooklets), (Fig. 22). Mature proglottids of both species are longer than wide and possess a prominent lateral genital pore. Grossly, the proglottids of *T. saginata* and *T. solium* are morphologically identical, and the number of primary uterine branches need to be counted to identify the species. Proglottids may be pressed between two slides and backlighted in order to count the branches. This may be facilitated with clearing in lactophenol. If needed, the proglottids can be injected with India ink to enhance visualization of the uterine branches after clearing with lactophenol. Proglottids can also be cleared, mounted and stained with carmine to visualize the uterine branches. *Taenia saginata* has 12–30 primary uterine branches coming off one side of the central uterine stem, while *T. solium* has 7–13 primary uterine branches. The primary uterine branches of *T. saginata* tend to be thin, while those of *T. solium* tend to be thicker. *Taenia asiaticus* has morphologic features similar to both species, with proglottids similar to *T. saginata*, but an armed rostellum similar to *T. solium* (Fig. 23), (Ash and Orihel, 2007). In areas where *T. sui hominis* occurs with other species, the morphologic criteria need to be scrutinized in detail in combination with an epidemiologic investigation, since *T. sui hominis* appears nearly-identical to *T. saginata*.

Until a confident identification is made, it is imperative that laboratorians use proper PPE when handling unknown cestode proglottids, due to the infectious nature of *T. solium* eggs.

Fig. 21 *Taenia saginata* adult worm measuring 4 m in length. Note the small size of the scolex, and the mature proglottis (left end) that are longer than they are wide. Courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

Fig. 22 Scolex (head) and neck region of a *Taenia solium* adult. The scolex contains 4 suckers (arrow points to 1 of the 4) and a prominent snout (rostellum) with a row of hooklets. The suckers and hooklets are used for attachment to the small intestinal mucosa. The scolex of *Taenia saginata* also has 4 suckers but lacks the rostellum with hooklets. Courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

Fig. 23 Carmine-stained proglottids of *Taenia solium* (left) and *T. saginata* (right). The two species can be differentiated by counting the primary uterine branches that originate from one side of the uterine stem (marked by an “*”): *T. saginata* has 12–30 primary uterine branches, while *T. solium* has 7–13. Courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

Coproantigen testing

Coproantigen assays allow for *Taenia*-specific diagnosis targeting parasite metabolic byproducts in stool. Most platforms are an antigen-capture EIA using antibodies targeting somatic or excretory-secretory antigens. The specificity and sensitivity vary based on the platform and quality of reagents, but are generally high for a genus-level identification. Target antigens disappear from stool post-treatment, so coproantigen testing can be used to monitor treatment success (Mwape and Gabriël, 2014). Coproantigen assays are usually only available in large reference laboratories or laboratories in endemic areas.

Most coproantigen assays are only specific at the genus level, even though they are primarily used to detect *T. solium* in endemic areas. Researchers in Peru have developed an assay that uses polyclonal antibodies against whole-worm extract and excretory-secretory antigens from *T. solium* in a hybrid sandwich-EIA. This assay is reported to demonstrate 95% sensitivity and 100% specificity to *T. solium* with no apparent cross-reactivity to *T. saginata* or *T. suihominis* (Guezala et al., 2009).

Hymenolepis nana, *Hymenolepis diminuta* (hymenolepiasis)

Biology and epidemiology

Hymenolepiasis is a zoonotic cestode infection caused by rodent parasites of the genus *Hymenolepis*. Two species implicated in human disease are the “dwarf tapeworm” *H. nana* and the “rat tapeworm” *H. diminuta*. Both species have a nearly worldwide distribution, but are more commonly seen in children in resource-poor regions of the world (Thompson, 2015; Tiwari et al., 2014). *Hymenolepis nana* is more commonly reported due to its ability to directly infect a new host in the absence of an intermediate host. In developed countries, *H. diminuta* is very rare, and usually only seen in rural or degraded areas (Marangi et al., 2003).

In the natural life cycle, both *H. nana* and *H. diminuta* are intestinal parasites of rodents, and adults reside in the small intestine of the rodent host. Gravid proglottids typically disintegrate while in the lumen of the intestine and only eggs are usually shed in feces. Eggs are eaten by an insect intermediate host, commonly beetles, and the oncosphere develops into a cysticercoid larva. Rodents and humans become infected after eating insects harboring cysticercoid larvae. Children are at particular risk, due to their habit of putting objects, such as insects, in their mouths. *Hymenolepis nana* is unique in that it can bypass the intermediate host, and humans can also become infected by ingestion of eggs on contaminated fomites. In this direct cycle, the eggs hatch in the lumen of the small intestine to release an oncosphere, and the oncosphere invades an intestinal villus. After approximately 4 days, it develops into a cysticercoid larva. The cysticercoid larva ruptures, releasing it from the villus, and then attaches to the intestinal mucosa and develops in to an adult. Adult worms attach between intestinal villi of the mucosa using hooklets and an armed rostellum, much like the scolex of *Taenia solium*. The pre-patent period takes about 4 weeks (Thompson, 2015).

Pathogenesis, clinical presentation, and treatment

Hymenolepis spp. cause ongoing damage to the host during the cysticercoid stage of autoinfection (*H. nana*), as well as attachment of the adult worms to the intestinal mucosa (*H. nana* and *H. diminuta*) (Thompson, 2015). Infected patients are commonly thought to be asymptomatic, although *Hymenolepis* infection may result in poor growth and development in children, particularly in cases of heavy infection or in the presence of other parasitic infections. The anti-helminthic drug of choice is praziquantel, with niclosamide as an alternative therapy (Medical Letter, 2013).

Diagnosis

Hymenolepiasis is diagnosed by the finding of eggs in wet mounts of stool (Fig. 10). Because the proglottids usually disintegrate while in the lumen of the small intestine, they are rarely seen in clinical specimens. However, adult tapeworms are sometimes removed by endoscopy and can be identified by gross morphology (Fig. 24).

Eggs of *H. nana* are ovoid, measuring 30–47 µm in diameter and have a thin, hyaline shell. The oncosphere has six hooklets and is surrounded by a membrane with bipolar thickenings. Four to eight filaments arise from these polar thickenings and extend into the space between the oncosphere and the outer shell. Eggs of *H. diminuta* are larger, measuring 60–85 µm in diameter, and have a thicker outer shell. The membrane surrounding the oncosphere lacks polar filaments (Ash and Orihel, 2007).

Adults removed by endoscopy are relatively small compared to *Taenia* spp. and the diphylobothriid cestodes. *Hymenolepis nana* is 2.5–4.0 cm long and has a scolex with four suckers and an armed rostellum with a ring of 20–30 hooklets. *Hymenolepis diminuta* is larger, measuring 20–60 cm long, and has an unarmed scolex. In both species, gravid proglottids are wider than long and are usually obviously craspedote (overhanging, like roof shingles) (Ash and Orihel, 2007).

Dipylidium caninum (dipylidiasis, dog tapeworm disease)

Biology and life cycle

Dipylidiasis, also commonly referred to as dog tapeworm disease or double-pored dog tapeworm disease, is caused by the zoonotic cestode, *Dipylidium caninum*. The disease occurs worldwide, but the sparsity of case reports and the asymptomatic nature of most infections probably belies its true prevalence. Most published reports have come out of the United States, Europe, the Philippines, China, Japan, and Latin America (Cabello et al., 2011). Most case reports have been in diaper-aged children, probably due to astute observations of the parents in combination with diapers being an efficient collection apparatus.

Fig. 24 *Hymenolepis* sp. adult seen in the terminal ileum during colonoscopy. Note that the body is comprised of short proglottids. Courtesy of Dr. Steffen Muehldorfer.

The natural definitive hosts for *D. caninum* are primarily dogs and cats. Adults live in the small intestine of the definitive host, attached to the intestinal mucosa by the scolex, and gravid proglottids are shed into the environment in the feces. Proglottids, and eggs derived therefrom, are eaten by an insect intermediate host, predominately flea larvae and parasitic lice. Common intermediate hosts are cat and dog fleas (*Ctenocephalides* spp.), human fleas (*Pulex irritans*), and dog chewing lice (*Trichodectes canis*). In the arthropod host, the oncosphere develops into a cysticercoid larvae. Fleas are holometabolous insects, and infected flea larvae harbor the cysticercoid larvae through their metamorphosis to adulthood. Cats and dogs become infected after ingesting infected adult fleas and lice when they groom themselves (Cabello et al., 2011). Humans also become infected from the incidental ingestion of infected insects. Children are of particular risk due to their more intimate associations with pets (e.g., kissing, cuddling pets) and tendency to put things in their mouths.

Pathogenesis, clinical presentation, and treatment

Most infected patients are thought to be asymptomatic, although non-specific symptoms such as diarrhea, restlessness and abdominal discomfort may be noted (Cabello et al., 2011). Older children may complain of anal pain and itching. Treatment is primarily with praziquantel (Medical Letter, 2013). Niclosamide is an alternative anti-helminthic drug.

Diagnosis

The diagnosis of dipylidiasis is primary made by the gross morphology of proglottids shed in stool (Fig. 25). The proglottids are harder than other intestinal cestodes, so eggs and characteristic egg packets are not commonly seen in wet mounts of stool.

Adult tapeworms are 10–70 cm long, and proglottids seen in clinical specimens are usually single or in small chains. Gravid proglottids are longer than wide and have two genital pores, one on each lateral margin. Gravid proglottids can be upwards of 23 mm long, but as humans are atypical hosts, proglottids seen in clinical specimens are usually smaller (e.g., a few mm long), and have been described as resembling pumpkin seeds or rice grains (Fig. 25). Proglottids are compartmentalized and contain egg packets. The scolex is not usually recovered in clinical specimens, but in conical and has a retractile armed rostellum (Ash and Orihel, 2007). Proglottids submitted to a laboratory that resemble *D. caninum* should be dissected to look for characteristic eggs packets (Fig. 25) and to rule out the less common, but morphologically similar, members of the genera *Raillietina* and *Inermicapsifer* (Davis et al., 2019).

Egg packets observed in wet mounts of stool or liberated from proglottids contain 8–15 eggs on average. The eggs are thin-shelled and measure 25–40 µm in diameter. The oncosphere contains 6 hooklets (Ash and Orihel, 2007).

Miscellaneous cestode infections

Raillietina spp. (raillietiniasis)

Raillietina is a genus of cestodes that normally parasitize birds, rodents, lagomorphs, and non-human primates. Human infection is rare, but has been reported from Central and South America, Cuba, Iran, Japan, Southeast Asia, the Philippines, French Polynesia, Australia, and the United States (Hawaii). Human infection is believed to be acquired from the incidental ingestion of infected insects and other invertebrates that serve as the natural intermediate hosts (Davis et al., 2019; Sapp and Bradbury, 2020). Most cases have been reported from children, probably for the same risk factors and collection methods described for *D. caninum*.

The clinical picture of raillietiniasis is not well described. Most cases have been asymptomatic, but pediatric patients have presented with generalized intestinal symptoms such as nausea, vomiting, diarrhea, headaches, weight-loss, and retarded growth. Non-intestinal symptoms have been reported in children in Latin America, such as personality changes, convulsions, tachycardia, arrhythmia, and lipothymia. However, given the presence of other endemic parasitic diseases in this region, it is unclear whether those symptoms were caused by *Raillietina* (Acha et al., 1980). There is no defined treatment regimen for raillietiniasis, but praziquantel has been used with success (Davis et al., 2019).

Fig. 25 *Dipylidium caninum* proglottids (left; markings represent millimeters) and characteristic egg packet (right). Note the presence of a 6-hooked within each egg (arrow).

Fig. 26 (A) Egg pouches of *Raillietina* sp., liberated from a gravid proglottid. (B) Characteristic egg of *Bertiella* sp., demonstrating inner and outer shells. A hooked oncosphere (arrow) is housed within the inner shell. (A) Courtesy of Dr. Richard E. Davis.

Diagnosis of raillietiniasis is made by the gross morphology of adult worms and proglottids, and the morphology of eggs liberated from the proglottids. Grossly, the proglottids are very similar to those of *D. caninum*, and should be dissected to examine the eggs. The eggs are 25–35 μm in diameter and contain a six-hooked oncosphere. The eggs are contained within pouches that are roughly 250–300 μm in diameter on average (Fig. 26A) (Davis et al., 2019; Ash and Orihel, 2007). The proglottids, egg pouches, and eggs are morphologically indistinguishable from those of *Inermicapsifer madagascariensis*. The two genera can be separated by the morphology of the scolex; the scolex of *Raillietina* is armed with hooklets, while the scolex of *I. madagascariensis* is unarmed (Davis et al., 2019).

***Inermicapsifer madagascariensis* (*Inermicapsifer* infection)**

Inermicapsifer madagascariensis (syn. *I. cubensis*, *I. arvicanthidis*) is an enigmatic cestode parasite of rodents. The life cycle is not completely understood, but it is presumed the intermediate hosts are arthropods and that human infection occurs after the incidental ingestion of arthropods. Human infection has been reported in sub-Saharan Africa, Madagascar, Comoro Islands, Venezuela, and Cuba (Sapp and Bradbury, 2020; Goldsmid and Muir, 1972). Nearly all human cases have been in predominately asymptomatic young children, or children with generalized gastrointestinal symptoms (Goldsmid and Muir, 1972). Treatment for *Inermicapsifer* infections is praziquantel or niclosamide (Sapp and Bradbury, 2020).

The diagnosis of *I. madagascariensis* is made by the gross examination of adult worms and their proglottids passed in stool (Goldsmid and Muir, 1972). The proglottids, egg pouches, and eggs are morphologically indistinguishable from those of *Raillietina* (above). To separate the genera morphologically in regions where both occur, it is necessary to examine the scolex; the scolex of *Raillietina* is armed with hooklets, while the scolex of *I. madagascariensis* is unarmed (Davis et al., 2019).

***Bertiella* species (*bertiellosis*)**

Bertiellosis is a zoonotic cestode infection caused by members of the genus *Bertiella*. Most cases from humans have been attributed to *B. stuederi* in Africa, India, Southeast Asia, and South America and *B. mucronotata* in South America and Cuba, although a species-level identification can be challenging. The natural hosts are non-human primates, rodents, and Australian marsupials, and most of the published human cases are in children that have had some contact with monkeys (Lopes et al., 2015; Sharma et al., 2018). The intermediate hosts are oribatid mites, and human infection is believed to be acquired from the incidental ingestion of infected mites. Patients have presented with common gastrointestinal problems, including diarrhea, recurrent and chronic abdominal pain, anorexia, weight loss, vomiting, and constipation (Sharma et al., 2018). Praziquantel is the drug of choice (Sharma et al., 2018).

Diagnosis of bertiellosis is made by the morphologic analysis of proglottids shed in stool and eggs liberated from proglottids or observed in wet mounts of stool. Gravid proglottids of *Bertiella* spp. are broader than long and often craspedote. Eggs of *B. stuederi* are on average 45–50 μm in diameter; those of *B. mucronotata* are smaller at 38–41 μm in diameter. The eggs of both species have an external membrane, a middle envelope composed of mucin, and an inner chitinous shell in the form of a “pyriform apparatus” that contains the oncosphere which can have 6–12 hooklets in pairs (Fig. 26B) (Meyers et al., 2000).

***Mesocestoides* spp. (*mesocestoidiasis*)**

Mesocestoidiasis is an enigmatic zoonotic disease caused by cestodes in the genus *Mesocestoides*. Human infection is rare, and most cases have been reported from the United States, as well as Greenland, Japan, Korea, China, and Africa (Meyers et al., 2000; Fuentes

et al., 2003). The life cycle of *Mesocostoides* is not completely described, but it is believed to have a three-host cycle. The natural definitive hosts are carnivorous birds and mammals, especially cats and dogs. The first intermediate host is believed to be an arthropod or other invertebrate, but nothing has been successfully described, either in nature or under laboratory conditions. Eggs experimentally fed to natural intermediate hosts has not resulted in infection, supporting the three-host life cycle hypothesis. The second intermediate and paratenic hosts are small mammals, birds, and reptiles. The intermediate host harbors a larval stage called a tetrathyridium that is the infectious stage for the definitive host. Sometimes, tetrathyridia or acephalic adult worms will cause a proliferative disorder in the definitive host (Padgett and Boyce, 2004; Mathison and Pritt, 2018b).

The source of human infection is not always known, but is believed to be from the consumption of undercooked meat or other animal products harboring infectious tetrathyridia. A cluster of cases from Japan was linked to the consumption of raw snake and turtle organs and blood, but most of the US cases do not have a confirmed source of infection. Most patients are asymptomatic, but have presented with anorexia, abdominal colic, anemia, and irritability (Meyers et al., 2000). Praziquantel and niclosamide have been used to treat mesocostoidiasis (Meyers et al., 2000).

All human cases have been diagnosed by the morphologic analysis of proglottids shed in stool. Gravid proglottids and contain a large characteristic parauterine organ that contains the eggs (Meyers et al., 2000). The eggs are small, measuring 19–24 µm in length, and have a thin membranous wall surrounding the six-hooked oncosphere (Ash and Orihel, 2007).

Acanthocephalan infections

Macracanthorhynchus species, Moniliformis moniliformis (acanthocephaliasis)

Biology and epidemiology

Acanthocephaliasis is a rare to uncommon zoonotic infection caused by the acanthocephalans, commonly referred to as “thorny-headed worms”. Acanthocephalans are an enigmatic group of animals. While grossly they are somewhat similar to nematodes, they are more closely related to rotifers, or possibly nested within the phylum Rotifera proper (Garcia-Varela et al., 2000). Most cases of intestinal human infection have been attributed to *Macracanthorhynchus hirudinaceus*, *M. ingens*, and *Moniliformis moniliformis*. *Macracanthorhynchus hirudinaceus* and *M. moniliformis* are widespread and sporadic human cases have reported throughout much of the world, while to date cases of *M. ingens* have only been recorded from the eastern United States (Mathison et al., 2016).

Acanthocephalans have a complex two-host life cycle with a vertebrate definitive host and an arthropod intermediate host. The natural definitive hosts for *M. hirudinaceus* and *M. ingens* are pigs and raccoons, respectively, while the definitive hosts for *M. moniliformis* are rats, although a variety of wild and domestic animals may serve as definitive hosts for any of the worms. Adult acanthocephalans reside in the small intestine of their definitive host, embedded in the intestinal mucosa by means of an armed proboscis (Fig. 27). Like cestodes, acanthocephalans absorb nutrients through their tegument. Gravid females shed eggs into the environment via the feces. The eggs are fully embryonated and contain an infectious first-stage larva called an acanthor. Eggs are ingested by an intermediate host, which in nature are typically beetles, millipedes, and cockroaches for *M. hirudinaceus*, *M. ingens*, and *M. moniliformis*, respectively. In the hemocoel of the intermediate host, the acanthor molts and becomes the second-stage larva known as an acanthella. After 6–12 weeks, the acanthella develops into a cystacanth, which is the infectious stage for the definitive host. Most human cases are reported in young children, who are more likely to put objects, such as insects, in their mouths (Mathison et al., 2016).

Pathogenesis, clinical presentation, and treatment

The clinical presentation in humans may range from asymptomatic or mild infection, to severe painful disease (Mathison et al., 2016). The thorny proboscis may cause hemorrhage, ulceration and abdominal pain when inserted into the intestinal wall, and rarely, intestinal perforation may occur. Other symptoms include nausea, vomiting, hematochezia, anorexia, weight loss, diarrhea and constipation. Local and peripheral eosinophilia are common. Treatment is not well described. Patients have been successfully treated with mebendazole and pyrantel pamoate. Surgery and anti-bacterial drugs may be necessary in cases of intestinal perforation (Mathison et al., 2016).

Diagnosis

Acanthocephaliasis is diagnosed by the gross morphology of adult worms shed in stool (Fig. 27), and eggs derived therefrom. Eggs of acanthocephalans are rarely reported from wet mounts of stool.

Adult acanthocephalans are large pseudocoelomate animals. Adult females of *Macracanthorhynchus* spp. are 12–32 cm long while the males are smaller at 7–8 cm long. They are white to pale pink in colors and have wrinkles and depressions which may give the false impression of segmentation. *Moniliformis moniliformis* is slightly smaller and more slender, measuring 10–27 cm for females and 4–10 cm for males (Fig. 27). Adults of *M. moniliformis* have more pronounced pseudosegmentation and often appear beaded. Adults of all acanthocephalans have an armed proboscis, which in clinical specimens may be retracted and must be dissected to appreciate (Ash and Orihel, 2007; Meyers et al., 2000).

Eggs of *Macracanthorhynchus* species are morphologically indistinguishable from one another and measure 89–100 µm long by 50 µm wide. They have a thick, dark brown shell that has a rough texture. Eggs of *M. moniliformis* are slightly larger, measuring 90–125 µm long by 65 µm wide and have a thick, smooth, clear shell (Fig. 27) (Ash and Orihel, 2007).

Fig. 27 Eggs and adult acanthocephalans. *Moniliformis moniliformis* adults (left) have pseudosegmentation, sometimes with a beaded appearance. They have a small armed proboscis (upper right) which is often retracted in adult worms submitted for examination. The eggs of *M. moniliformis* have a thick, smooth clear shell (right, middle panel), whereas those of *Macracanthorhynchus* have a thick, dark brown shell that has a rough texture (lower right). Both eggs contain a larva (acanthor) with rostellar hooks. The *Macracanthorhynchus* egg is courtesy of Phong Duong.

Parasites of the appendix and large intestine, and anus

Like the small intestine, there are a large number of protozoa and helminths that can infect the large intestine (Table 4). Some such as *Entamoeba histolytica*, *Balantidioides coli*, and *Schistosoma* spp. are responsible for a significant amount of human morbidity and mortality in endemic regions of the world.

Protozoan infections

Entamoeba histolytica (intestinal amebiasis)

Biology and epidemiology

Clinical amebiasis is caused by *Entamoeba histolytica*, one of 11 species of amebae, and one of nine species of the genus *Entamoeba*, that inhabit the human GI tract (Hooshyar et al., 2015). *Entamoeba histolytica* belongs to a complex of four morphologically-identical species, the others being *E. dispar*, *E. bangladeshi*, and *E. moshkovskii*. Other nonpathogenic intestinal amebae will be discussed elsewhere in the chapter. Historically, *E. histolytica* was considered the only pathogenic *Entamoeba* in the human host, however, the pathogenic role of *E. bangladeshi* and *E. moshkovskii* is not completely understood (Ali, 2015).

Entamoeba histolytica has a worldwide distribution, with clinical disease being most prevalent in resource-poor regions of Latin America, Africa, and Asia. Most patients in the US and Europe with clinical amebiasis are returning travelers, particularly from South America, the Middle East, and Southeast Asia. In developed nations, the prevalence in non-travelers is highest in MSM, immunocompromised patients, and institutionalized patients (Shirley et al., 2018). Overall, the global burden is difficult to define due to a lack of specificity in many of the diagnostic assays. The WHO estimates that there were 103,943,952 cases in 2010, with 27,553 deaths (Kirk et al., 2015). *Entamoeba dispar* also has a worldwide distribution and non-human primates may serve as reservoir hosts (Hooshyar et al., 2015). The epidemiology of *E. moshkovskii* and *E. bangladeshi* is less understood. Cases of *E. moshkovskii* have been sporadically reported from the US, Latin America, the Middle East, Africa, Australia, and Southeast Asia, with higher prevalence in Australia, India, Bangladesh, Tanzania, Pakistan, and Iran (Ali, 2015; Lopez et al., 2015). *Entamoeba bangladeshi* is endemic to Southeast Asia and sub-Saharan Africa (Ngoben et al., 2017).

Members of the *E. histolytica*-complex have a simple one-host life cycle. Trophozoites multiply by binary fission in the lumen of the large intestine. Both cysts and trophozoites are shed into the environment via the feces (Fig. 1). Infection is initiated by the ingestion of mature cysts in fecal-contaminated food, water, and fomites or via anal-oral sex. The amebae excyst in the small intestine and migrate to the lumen of the large intestine. Although trophozoites usually reside in the colonic lumen and feed on bacterial flora, *Entamoeba histolytica* has the ability to adhere to colonic mucins via the Gal/GalNAc lectin and then degrade the

Fig. 28 Intestinal amebiasis with ulceration. Image A depicts a section of resected colon which has been opened to reveal the mucosa. Several ulcers and a region of perforation are clearly visible. By histopathologic examination, the ulcers classically have a “flask-shape” (B). This occurs as trophozoites invade through the intestinal mucosa and then invade laterally into the underlying submucosa, producing an ulcer apex (marked by an “*”) that is narrower than the ulcer base. Images courtesy of the U.S. Centers for Disease Prevention and Control Public Health Image Library.

protective colonic mucous barrier using glycosidases and other enzymes (Kantor et al., 2018). Trophozoites may then penetrate the colonic epithelium, causing erosions, ulcerations, mass-like lesions (ameboma), and rarely, perforation (Fig. 28A). Trophozoites may also enter the circulation and infect other sites. The most common site of extraintestinal infection is the liver, followed by the brain and lungs (Shirley et al., 2018). Hepatic amebiasis will be discussed elsewhere in the chapter.

Pathogenesis, clinical presentation, and treatment

The majority (~90%) of cases of *E. histolytica* infection are asymptomatic (Kantor et al., 2018). When present, intestinal manifestations may range from mild watery diarrhea, to bloody diarrhea, to severe dysentery and even fulminant necrotizing colitis due to invasion of the trophozoites into the intestinal wall. Fever and abdominal pain are common with invasive disease. Complications include toxic megacolon and perforation, as well as formation of an ameboma which may cause partial obstruction or mimic malignancy. Risk factors for severe disease include extremes of age, immunocompromised state, alcoholism, malnutrition, and pregnancy (Kantor et al., 2018). Treatment of infection is warranted even in cases of asymptomatic disease, to prevent the spread of infection to other individuals. The treatment regimen varies by the type of disease. Noninvasive colonic colonization is treated only with a luminal agent such as paromomycin, iodoquinol, or diloxanide furoate to eradicate the cyst form of the organism (Medical Letter, 2013). For cases of invasive and/or disseminated disease, metronidazole or tinidazole is added to the regimen.

Diagnosis

The diagnosis of intestinal amebiasis can be accomplished by O&P examinations of stool, histopathology, antigen detection, antibody detection, and molecular diagnosis. In specialized reference labs, methods such as culture or isoenzyme analysis may be available.

Microscopy

The traditional diagnosis of amebiasis is the detection of *E. histolytica* cysts and trophozoites in O&P examinations of stool. Unfortunately, in most cases, the morphologic features are inadequate for reliably separating *E. histolytica* from non-pathogenic members of the complex. Trophozoites of *E. histolytica* measure 10–60 μm in size, with pathogenic strains typically greater than 20 μm (Fig. 1). They possess a single nucleus with evenly-distributed peripheral chromatin and a discrete, usually centrally-located, karyosome. The cytoplasm is finely granular and may include bacteria, yeast, or erythrocytes. The presence of ingested erythrocytes is considered pathognomonic for *E. histolytica*, and is the only morphologic feature that allows for a presumptive species-level identification by stool microscopy. Pseudopodia may also be present. The cysts of *E. histolytica* are 10–20 μm in diameter (Fig. 1). Immature cysts typically have a large single nucleus, a large glycogen vacuole, and irregularly-shaped peripheral chromatoid bodies. Mature cysts have four small nuclei and the chromatoid bodies are broad and bluntly-rounded. Members of the *E. histolytica*-complex cannot be separated by cyst morphology (Ash and Orihel, 2007).

Trophozoites can also be detected in intestinal biopsy specimens processed for histopathology. *E. histolytica* classically forms “flask-shaped” ulcers in the colonic mucosa, in which the apex of the ulcer in the epithelium is narrower than the base in the submucosa (Fig. 28B). The trophozoites are morphologically similar to those observed in stool, although with a higher prevalence of ingested erythrocytes. *Entamoeba* observed in intestinal biopsy specimens or extraintestinal sites can be reported as *E. histolytica* at the species level as it is the only species that can invade tissue and become systemic. Cysts are not observed in extraintestinal specimens (Mathison and Pritt, 2018a).

Antigen detection

There are several commercially-available antigen detection assays for the diagnosis of intestinal amebiasis. There are several platforms available, including EIA, DFA, and lateral flow immunochromatography, and a few will simultaneously detect other intestinal protozoa such as *Giardia duodenalis* and *Cryptosporidium* spp. (Garcia et al., 2018). In general, these assays have good sensitivity and specificity, but they require fresh or frozen unpreserved stool and some were developed using trophozoite-specific antigens and may have false negative results in stool in which only cysts were shed (Garcia et al., 2018; Ali, 2015). Also, some assays are unable to distinguish between *E. histolytica* and *E. dispar* (Ali, 2015).

Antibody detection

Antibody detection is primarily used for diagnosis of extraintestinal infection of *E. histolytica* and is not sensitive for diagnosing non-invasive intestinal illness. Most commercially-available assays are EIA. These tests have a high sensitivity (greater than 90%) for extraintestinal infections, but only about 70% for invasive intestinal infection. Also, because IgG antibodies to *E. histolytica* persist over time, a positive result cannot distinguish between current and past infections, and patients who are from, or spent substantial time in, highly endemic areas may be positive due to past exposure (Ali, 2015).

NAATs

NAATs are available in both single analyte and multiplex formats. While the former are not widely used outside of specialized reference and research centers, there are now several commercially-available, easy-to-use multiplex assays that detect *E. histolytica* that have FDA or CE approval, and these assays are increasingly used in the clinical microbiology laboratory in developed countries. Multiplex assays may have slightly lower sensitivity than monoplex NAATs, but still have a higher sensitivity than morphologic analysis or antigen detection, and have become a test of choice for rapidly evaluating patients with infective diarrhea in some settings. Unfortunately, the relatively high cost of these multiplex molecular panels tends to be cost-prohibitive outside of large reference labs or health care systems that have consolidated testing. It is also important to note that some of these multiplex assays may not be able to distinguish *E. dispar* from *E. histolytica* when the former is in higher concentrations (Ali, 2015; Garcia et al., 2018). Regional reference laboratories may have specialized NAATs for the diagnosis or differentiation of *Entamoeba* species. The CDC in conjunction with researchers in Brazil developed a proof-of-concept Luminex[®]-based assay that can detect *E. histolytica*, *E. dispar*, *E. moshkovskii*, *E. coli*, and *E. hartmanni* (Santos et al., 2013). The CDC also offers a confirmatory real-time PCR to separate *E. histolytica* from *E. dispar* in stool specimens positive by morphologic analysis (Qvarnstrom et al., 2005). LAMP-mediated assays show promise in increasing simplicity and lowering the cost of molecular diagnosis (Ali, 2015).

Dientamoeba fragilis (Dientamoeba infection)

Biology and epidemiology

Dientamoeba fragilis is an enigmatic protozoan. While morphologically similar to amebae, it is actually a flagellate and is more closely related to *Trichomonas vaginalis* and *Pentatrichomonas hominis* than it is to other protozoa that parasitize humans. Unlike other trichomonads, the flagella of *D. fragilis* are internalized and the organism moves via pseudopodia like amebae. *Dientamoeba fragilis* occurs worldwide, but the prevalence varies by region depending on the diagnostic method. It is unusual in that its prevalence is higher in developed countries, probably due to improved diagnostic techniques. There are currently two recognized genotypes, genotype 1 and genotype 2, the former of which is more common in clinical specimens (Stark et al., 2016).

There has been controversial debate in recent years as to the nature of the life cycle of *D. fragilis* and how it is transmitted to humans. For decades, it was believed that *D. fragilis* lacked a cyst stage, which is typical for trichomonads, and that infection occurred from the ingestion of trophozoites or was carried passively by other parasites, such as in *Enterobius vermicularis* (pinworm) eggs. The pinworm theory has for the most part been abandoned, but in recent years the description of precyst and cyst stages in mouse models and detection of such cysts in human clinical specimens has been proposed (Munasinghe et al., 2013; Stark et al., 2014). It should be noted that these claims are still not universally accepted among protozoologists and eukaryotic taxonomists. The role of animals in the transmission of *D. fragilis* is also not well understood. While generally considered a human parasite, *D. fragilis* has been reported from non-human primates and domestic pigs (Stark et al., 2016). Regardless of the mode of transmission, *D. fragilis* resides in the lumen of the intestine where it multiplies by binary fission and feeds on bacteria, yeast, and other organic material in the fecal stream. There is no evidence to date on whether *D. fragilis* can invade the intestinal epithelium and the pathogenic status of the organism remains unresolved.

Pathogenesis, clinical presentation, and treatment

The role of *D. fragilis* as a pathogen remains controversial, despite the large body of evidence from clinical studies showing its association with symptomatology and resolution of symptoms following treatment (Stark et al., 2016). Although it is clear that many infected patients are asymptomatic, the clinical manifestations range from acute and chronic abdominal pain, diarrhea, and constipation. Eosinophilia has been reported in up to 50% of infected patients (Stark et al., 2016). There is no well-accepted treatment regimen for *D. fragilis* infection. Commonly used antiparasitic drugs include paromomycin, iodoquinol, metronidazole, tinidazole, and tetracycline (Stark et al., 2016; Medical Letter, 2013).

Diagnosis

Infection is diagnosed primarily by the detection of trophozoites in permanently-stained fecal smears. If they exist, cyst forms are likely to be rare and difficult to detect. Culture and PCR may be available in large or specialized reference laboratories. There are currently a few commercially-available multiplex NAATs that include *D. fragilis* as a target; they all have CE approval, but to date none are FDA-approved or cleared for in vitro diagnostic use in the United States.

Trophozoites of *D. fragilis* measure 5–15 µm and possess one or two nuclei, with binucleate forms predominating (Fig. 1). The nuclei contain a mass of karyosomal material that is often in a cluster of 4–8 granules; there is no peripheral chromatin. The cytoplasm is finely to heavily granular and often contains bacteria and yeast. Motility is non-progressive and a thin, nearly transparent pseudopod may be evident extending from the cytoplasm (Ash and Orihel, 2007).

Balantioides coli (balantiosis)

Biology and epidemiology

Balantiosis (also known as balantidiasis) is caused by *Balantioides coli*, the largest parasitic protozoan, and only ciliated protozoan, of humans. This species has a complicated taxonomic history. It was originally described in 1857 in the genus *Paramecium* from two patients presenting with dysentery. It was transferred to *Balantidium* in 1863. In 1931, the genus *Balantioides* was described to accommodate the parasite, but unfortunately that name apparently went unnoticed for decades and *Neobalantidium* was described in 2013 to accommodate *B. coli*. In 2014, attention was brought to the original description of *Balantioides*, and in 2018 *Balantioides* was restored as the valid genus to accommodate *B. coli* (Mathison and Pritt, 2020). To complicate matters, *B. coli* is sometimes incorrectly placed in the genus *Balantidioides*, which is a genus of endosymbiotic ciliates.

Balantidioides coli is uncommonly reported, but has a worldwide distribution. Many mammal species can serve as hosts for *B. coli*, but pigs are a common reservoir for human infection, and human cases are more common in resource-poor areas that engage in pig farming. Areas of higher prevalence include Latin America (especially the Altiplano region of Bolivia), Philippines, New Guinea, and the Middle East (Schuster and Ramirez-Avila, 2008).

Balantioides coli has a simple, one-host life cycle. Infection occurs from the ingestion of cysts in fecal-contaminated food, water, and fomites. The parasite excysts in the small and large intestine and multiplies by binary fission in the lumen of the large intestine. Both cysts and trophozoites are shed in stool, but only cysts are infectious for a new host. Like *Entamoeba histolytica*, *Balantioides coli* can invade the colonic mucosa, and may rarely cause ectopic infection. Regardless, most cases of *B. coli* reported from respiratory specimens are believed to be misidentifications of ciliocytophthoria, a condition whereby motile ciliated epithelial cells and ciliary tufts detach and are observed in fresh bronchial washings and BALs (Schuster and Ramirez-Avila, 2008).

Pathogenesis, clinical presentation, and treatment

The pathogenicity of *Balantioides coli* is not well understood. Trophozoites may be able to invade the intestinal mucosa through the use of proteolytic enzymes such as hyaluronidases (Schuster and Ramirez-Avila, 2008). Many infected individuals are asymptomatic, or experience only mild abdominal pain and watery diarrhea. Extensive intestinal invasion can result in fulminating disease with bloody diarrhea, dysentery, tenesmus, and weight loss. Fatalities have been caused by intestinal hemorrhage and perforation (Schuster and Ramirez-Avila, 2008). Risk factors for severe disease include malnourishment, immune compromise, achlorhydria, alcoholism, and concurrent chronic diseases (Schuster and Ramirez-Avila, 2008). Treatment is with tetracycline, metronidazole, or iodoquinol (Schuster and Ramirez-Avila, 2008; Medical Letter, 2013).

Diagnosis

The diagnosis of balantiosis is made primarily by the finding of cysts and trophozoites in wet mounts of stool, less commonly in permanent-stained stool specimens (Fig. 29). Trophozoites measure 50–200 µm long by 40–70 µm wide. Living trophozoites in fresh wet mounts move by a rotary, boring motion with the cilia maintaining a constant, synchronized motion. Trophozoites taper to the anterior end where a prominent cystostome is located. There are two nuclei, a large kidney-shaped macronucleus and a smaller micronucleus, the latter of which can be difficult to discern. The cytoplasm may contain ingested debris and food vacuoles. Cysts are spherical and measure 50–70 µm in diameter. Cilia may be visible under the thick cell wall. Both the macronucleus and micronucleus are present. Because ingested objects are not expelled during encystment, food and vacuoles may be seen in the cysts as well (Ash and Orihel, 2007).

Trophozoites of *B. coli* can be observed in colonic biopsy specimens, usually in relation to flask-shaped ulcers like those described for intestinal amebiasis. The trophozoites in biopsy specimens share the same morphologic features as those seen in stool specimens (Mathison and Pritt, 2018a).

Blastocystis spp. (blastocystosis)

Biology and epidemiology

Blastocystosis is caused by enigmatic protozoan parasites in the genus *Blastocystis*. Historically, the genus has been allied with yeasts, amebae, and coccidians, but is now believed to be a stramenopile in the Stramenopiles-Alveolates-Rhizaria (Sar) super-group (Adl et al., 2019). Traditionally, species have been described based on the host (e.g., *B. hominis* from humans, *B. ratti* from rats) and historically all isolates of humans were referred to as *B. hominis*. However, molecular analyses appear to demonstrate that there is no population unique to humans and all human isolates appear to have animal reservoirs. Nine (possibly ten) primary subtypes have been found in mammals and birds, with subtypes 1 and 3 making up most of the cases of human blastocystosis (Stensvold et al., 2007).

Fig. 29 *Balantioides coli* cyst (A) and trophozoite (B), (unstained wet preparation, 400 $\times$). Note the large ‘kidney bean-shaped’ macronucleus (best seen here in the cyst) and the circumferential cilia on the trophozoite. Images courtesy of the U.S. Centers for Disease Control and Prevention.

The life cycle of *Blastocystis* is not completely understood, and several models have been proposed. In a recent proposal, vacuolar forms (which includes both the “vacuolar” and “cyst-like” forms in historical nomenclature) reproduce by binary fission in the lumen of the large intestine. These vacuolar forms can become cysts, and both vacuolar forms and cysts are shed into the environment via the feces, however it is believed only the true cyst forms are infectious for a new host. After ingestion of cysts in fecal-contaminated food, water, and fomites, the parasite excysts and becomes a granular form, which is a precursor to the vacuolar form. It has also been suggested that in the lumen of the host’s large intestine, the parasite can become an amoeboid form which plays a role in pathogenesis. This belief is still not generally accepted, however, as these amoeboid forms might simply be aberrant vacuolar forms (Tan, 2008).

Pathogenesis, clinical presentation, and treatment

The potential pathogenicity of *Blastocystis* is unclear. Infection has been associated with a variety of symptoms, among which abdominal pain and diarrhea are most common (Tan, 2008). Other symptoms include anorexia, abdominal bloating, increased flatulence, nausea, urticaria, and the irritable bowel syndrome. Risk factors for symptomatology may include immune compromise and parasite genotype, although this warrants further study (Tan, 2008). There is no evidence that *Blastocystis* can invade tissue, but presumed colonization of invasive and extraintestinal lesions due to other pathogens has been described (Tan, 2008). There is no widely-accepted treatment regimen, but metronidazole, trimethoprim sulfamethoxazole and nitazoxanide have been used with varying degrees of success (Sekar and Shanthi, 2013).

Diagnosis

The diagnosis of blastocystosis is primarily made by the finding of organisms in O&P examinations of stool. Molecular diagnosis may be available at large reference laboratories, and there are a couple commercially-available multiplex assays that include *Blastocystis* as a target. These assays currently are CE marked, but not FDA approved/cleared.

The most common stage of *Blastocystis* observed in stool specimens is the vacuolar form, which includes the traditional descriptions of both vacuolar and cyst-like forms (Fig. 30). The vacuolar form is highly variable in size, measuring 4.0–63.0 μm in diameter in human stool specimens. A large central vacuole takes up approximately 90% of the body, with the nuclei and other organelles located within a thin rim between the vacuole and outer cell wall. Traditionally, the “cyst-like” forms tend to be smaller and have a larger rim containing the nuclei and organelles, whereas the traditional vacuolar forms are larger and have a very thin rim around the central vacuole. Dividing forms may be seen in permanent stained smears (Tan, 2008). In specimens stained with Wheatley’s trichrome, the central vacuole typically stains blue-green while the nuclei and other organelles stain red-purple (Ash and Orihel, 2007). The cyst, which is the most recently-described stage, is rarely reported from stool, probably due to its small size (2.0–5.0 μm) and unfamiliarity to diagnostic technologists (Tan, 2008). The cysts are ovoid and contain 1–4 nuclei. Due to the historic unfamiliarity of this stage, it is possible it has been misidentified for years as cysts of *Endolimax nana* or *Enteromonas hominis*. Because the taxonomy of *Blastocystis* is in a state of flux, it is becoming more common for diagnostic laboratories to report *Blastocystis* at the genus-level only rather than *B. hominis*. As with leukocytes and erythrocytes, it is common practice to report the relative quantity of *Blastocystis* forms (e.g., rare, few, moderate, many), as the quantity may be positively associated with symptoms (Garcia et al., 2018).

Fig. 30 Vacuolar form of three *Blastocystis* sp. parasites (Wheatley's trichrome stain, 1000 $\times$). Note the large central vacuole and peripheral nuclei (arrows).

Non-pathogenic intestinal protozoa

The following protozoa inhabit the human intestinal tract as commensals but do not cause disease. It is important for laboratorians and diagnosticians to learn to recognize them and distinguish them from potentially pathogenic species (Figs. 1 and 8). It is also helpful to report nonpathogenic protozoa, especially in symptomatic patients, as it could be an indicator of exposure to fecal-contaminated food or water sources, even if the protozoan is not the cause of disease. It would be helpful such reports indicated which species were not pathogenic or otherwise provided guidance for treating physicians to prevent undue burden and costs of unnecessary treatment (Lee et al., 2000).

Entamoeba hartmanni

Entamoeba hartmanni is a small nonpathogenic ameba with a worldwide distribution. It has many morphologic characteristics in common with *E. histolytica*, and historically has been referred to as a "small race" of *E. histolytica*. In cases where members of the *E. histolytica*-complex are on the small end their size range, separation from *E. hartmanni* can be challenging. Trophozoites measure 8–12 μm but are usually consistently less than 10 μm . They have single nucleus with even peripheral chromatin and a discrete, usually centrally-located karyosome. Mature cysts are 5–10 μm , have four nuclei, and spherical to elongate chromatoid bodies with blunt ends (Ash and Orihel, 2007).

Entamoeba coli

Entamoeba coli has a worldwide distribution and is one of the most commonly reported *Entamoeba* species in clinical specimens. Non-human primates may serve as reservoir hosts. Trophozoites of *E. coli* measure 15–50 μm and have a single nucleus with irregular peripheral chromatin and a usually eccentric karyosome. The cytoplasm is often described as "dirty" and may contain vacuoles and ingested food particles, including bacteria, yeast, and even other intestinal protozoa. Cysts are 10–35 μm in diameter. Immature cysts typically have a large glycogen vacuole and two nuclei. Mature cysts have eight nuclei, with hypernucleate forms having 16 or more nuclei. The presence of an *Entamoeba* cyst in human stool with more than four nuclei is pathognomonic for *E. coli* (Ash and Orihel, 2007).

Entamoeba polecki and *E. chattoni*

Entamoeba polecki and *E. chattoni* are enigmatic zoonotic *Entamoeba* species. The epidemiology of these two species is not well described. *Entamoeba polecki* is primarily a parasite of pigs and monkeys and has spots of endemicity in Venezuela, Guinea, Iran, and Southeast Asia, where the prevalence in Papua New Guinea can reach 30% (Hooshyar et al., 2015; Verweij et al., 2001). *Entamoeba chattoni* is normally a parasite of non-human primates and is endemic to Africa (Hooshyar et al., 2015). Both species morphologically identical and in areas where both species occur may be difficult to separate. Cysts are 9–24 μm in diameter; the single nucleus (rarely binucleate forms may be seen) is large in relation to the cytoplasm and has variable peripheral chromatin and a karyosome that can be minute to large or even obsolete. Cysts often contain a large inclusion mass that usually stains grey to green with Wheatley's trichrome. Chromatid bodies are numerous and highly variable in size and shape. Trophozoites measure 10–25 μm and contains a single large nucleus with characteristics similar to those of the cysts. The trophozoites can be difficult to separate from other *Entamoeba* spp. (Ash and Orihel, 2007).

Endolimax nana and Iodamoeba buetschlii

Endolimax nana and *Iodamoeba buetschlii* are common and widespread nonpathogenic amebae. The cysts of *E. nana* are 5–10 µm and have four small nuclei with a large karyosome and no peripheral chromatin. There are no chromatoid bodies present. Cysts of *I. buetschlii* are 5–20 µm and have a large single nucleus with a large karyosome and no peripheral chromatin. As with *E. nana*, chromatoid bodies are not present. A unique characteristic of the cysts of *I. buetschlii* is the presence of a large glycogen mass that appears red-brown in wet mounts of stool stained with iodine. In permanent-stained smears, this glycogen mass does not take up stain, but is evident as a colorless, well-defined mass. The trophozoites of both species are nearly identical and possess a single nucleus with a large karyosome and no peripheral chromatin. The published size ranges are slightly different; trophozoites of *E. nana* are 6–12 µm while those of *I. buetschlii* are slightly larger at 8–20 µm. When cysts are not present, the two species can be difficult to separate. Luckily neither is pathogenic (Ash and Orihel, 2007; Poulsen and Stensvold, 2016).

Chilomastix mesnili

Chilomastix mesnili is a nonpathogenic flagellate of the human large and small intestine that occurs worldwide. Like most nonpathogenic intestinal protozoa, it has a simple one-host life cycle whereby infection occurs from the ingestion of cysts and trophozoites multiply by binary fission in the lumen of the intestine. Trophozoites are usually pyriform and measure 6–24 µm long. They have a large, single, anteriorly-located nucleus that contains a small karyosome and granular, fragmented peripheral chromatin. In permanent-stained specimens, the cytostome and fibrils may be evident. *Chilomastix* has three anterior flagella which are not usually visualized on stained smears. Trophozoites may not stain well and often round-up in improperly-preserved specimens, which could cause issues in microscopic detection. Cysts are uninucleate, lemon-shaped, and measure 6–10 µm in length. Fibrils are usually prominent and give the appearance of a “safety pin” alongside the cytostome (Ash and Orihel, 2007).

Pentatrichomonas hominis

Pentatrichomonas (formerly *Trichomonas*) *hominis* is a cosmopolitan nonpathogenic flagellate of the human large intestine. Its prevalence is unknown and the species is probably underreported. Other mammals may serve as reservoir hosts, including non-human primates, dogs, cats, foxes, rabbits, cattle, sheep, goats, and deer (Li et al., 2018, 2016, 2017). Like other trichomonads, there is no known cyst stage and infection is believed to occur from the ingestion of trophozoites on fecal-contaminated fomites. Trophozoites are pyriform and measure 6–20 µm long. The nucleus is elongated and in the anterior portion of the organism. They possess five flagella: four anterior and a fifth that runs along the outer margin of an undulating membrane and extends beyond the posterior end of the organism. Flagella are usually visible in stained smears. Trophozoites also possess a prominent axostyle that extends beyond the posterior end of the organism (Ash and Orihel, 2007).

Enteromonas hominis and Retortamonas intestinalis

Enteromonas hominis and *Retortamonas intestinalis* are two species of widespread but uncommonly reported nonpathogenic intestinal flagellated protozoa. Their scarcity in reports may be due to their small size, unfamiliarity to laboratorians, or misidentification of other small protozoa such as *E. nana* and *C. mesnili* due to some morphologic similarities. Like *C. mesnili*, they have a simple life cycle whereby infection occurs from the ingestion of cysts and trophozoites multiply by binary fission in the lumen of the intestinal tract. Trophozoites of *E. hominis* are rounded to oval and measure 6–8 µm long. They have an anterior, single nucleus with a large karyosome and four flagella, three anterior and one posterior. The flagella can be visualized in stained smears. Cysts of *E. hominis* are ellipsoidal and measure 4–8 µm long. They may possess 1, 2, or 4 nuclei; when two or four nuclei are present, they usually have a bipolar arrangement. Trophozoites of *R. intestinalis* are pyriform to rounded and measure 4–10 µm long and have a single, anterior nucleus with a small karyosome. There are two flagella present, one anterior and one posterior. The cysts of *R. intestinalis* are ovoid and measure 4–7 µm long. Mature cysts have a single nucleus with a compact karyosome and prominent fibril (Ash and Orihel, 2007).

Nematode infections

Enterobius vermicularis (enterobiasis, pinworm infection)

Biology and epidemiology

Enterobiasis, commonly referred to as pinworm infection, is a cosmopolitan disease caused by *Enterobius vermicularis*. It is one of the most common helminth infections worldwide; it is estimated there are 40 million people infected at any one time in the United States alone. The disease is seen most commonly in patients under the age of 18 years old and in institutional settings, day care centers, and other crowded environments, and usually occurs in families (Rawla and Sharma, 2020). There is a 2:1 ratio of males to females infected. Prevalence varies from country to country based on availability of testing procedures and reporting regulations. The true global burden is not known.

Enterobius vermicularis has a simple one-host life cycle and humans are the only known host. Adults live in the lumen of the large intestine. At night, gravid females migrate to the anal opening and deposit partially-embryonated eggs in the perianal folds. Eggs embryonate quickly and within approximately 4 h are already infectious for the next host. This is in marked contrast to most other intestinal nematodes, which must embryonate in the environment over a period of days to weeks. Enterobiasis occurs from the ingestion of fully-embryonated eggs on fomites, including hands, clothing, bedding, furniture, and personal care products.

Enterobiasis can be complicated to control after an environment becomes contaminated. Eggs hatch in the small intestine and migrate to the large intestine where they become adults. Ectopic colonization of the appendix is not uncommon (Rawla and Sharma, 2020). On rare occasions in female patients, after oviposition, the female worms will accidentally enter the urogenital tract and cause ectopic infection of the vulva, vagina, uterus, fallopian tubes, and ovaries (Choudhury et al., 2017).

Pathogenesis, clinical presentation, and treatment

An estimated 1/3 of infected individuals are asymptomatic (Rawla and Sharma, 2020). The most common symptom is nighttime anal itching (“nocturnal pruritis ani”) due to the presence of the adult female and eggs in the perianal area. Heavy infections may cause insomnia, daytime sleepiness and irritability. Appendicitis, vulvovaginitis, salpingo-oophoritis, and pelvic inflammatory disease may be caused by ectopic migration of adult worms. Drugs of choice include albendazole, mebendazole, or pyrantel pamoate (Medical Letter, 2013).

Diagnosis

Enterobiasis is diagnosed by the detection of eggs (and occasionally adult females) on cellulose tape preparations and specialized collection devices, and rarely, by histopathology. Unlike other intestinal nematodes, eggs of *E. vermicularis* are only rarely reported from concentrated wet mounts of stool.

The traditional method of diagnosis is the “cellulose tape test” whereby non-frosted cellulose tape is applied to the perianal area of suspect patients in the early morning hours before showering and defecation and examined microscopically for the presence of eggs. Nowadays there are commercial collection kits available, including the SWUBE™ (Becton Dickinson, Franklin, New Jersey) and the Pinworm Collector (Scientific Device Laboratory, Des Plaines, Illinois) (Carroll et al., 2019). Eggs of *E. vermicularis* are 50–60 µm long by 20–30 µm wide, are flattened on one side, and have a thick hyaline shell (Fig. 10). Eggs are partially-embryonated when observed on paddles, cellulose tape, or in wet mounts of stool (Ash and Orihel, 2007).

Adult females of *E. vermicularis* are commonly submitted to diagnostic laboratories when observed grossly in stool specimens, around the perianal folds during clinical evaluation, in colonic washings, and by colonoscopy (Fig. 11). Adult males are rarely seen due to their small size; they are small enough that they may be observed in concentrated wet mounts of stool. Adult females are 8.0–13.0 mm long and have cephalic inflations and a characteristic pointed tail (Fig. 31). Males measure 2.5 mm long and also have cephalic inflations, but have a bluntly-rounded tail (Ash and Orihel, 2007).

Adult females of *E. vermicularis* observed in appendix and intestinal biopsy specimens have distinct morphology that usually does not cause diagnostic problems. They have large platymyarian muscle cells, a strongly-muscled esophagus, and characteristic lateral alae on the cuticle that are formed from ridges that run along the external body of the worm. The uterine tubes of gravid females are usually loaded with characteristic eggs (Mathison and Pitt, 2018a).

Fig. 31 Adult female *Enterobius vermicularis*. Note the characteristic pointed tail, from which the term “pinworm” comes. The uterus if full of eggs (inset). From Mathison BA and Pitt BS (2018) Chapter 5: Parasitic Diseases. In: *Atlas of Fundamental Infectious Diseases Histopathology: A Guide for Daily Practice*. Pitt BS (ed.). Pathologists: Northfield, IL: College of American.

***Trichuris trichiura* (trichuriasis, whipworm infection)**

Biology and epidemiology

Trichuriasis, commonly referred to as whipworm infection, is caused by *Trichuris trichiura*, a nematode with a nearly worldwide distribution. The zoonotic potential of *T. trichiura* is not well understood. Historically, *Trichuris* species were classified based on host data, but as more genotyping data becomes available, it is unclear whether there are multiple species infecting humans or whether other animals, such as nonhuman primates and pigs, can harbor *T. trichiura* and serve as a reservoir for human infection (Betson et al., 2015). Classified as a “soil-transmitted helminth” (STH) along with *Ascaris lumbricoides* and hookworms, *T. trichiura* is believed to infect around 2.8 million people worldwide, especially in resource-poor countries in the tropics and subtropics (Flueckiger et al., 2019). Human infection is primarily a disease of poverty where there is inadequate waste disposal and limited access to clean water (Else et al., 2020). According to the WHO, *T. trichiura* was responsible for 337,000 years lost to disability worldwide in 2016 (WHO, 2020b). Prevalence of infection is greatest in children ages 5–15 years, and declines in older individuals.

Trichuris trichiura has a simple one-host life cycle. Adults reside in the large intestine and gravid females shed unembryonated eggs into the environment in the feces. After 15–30 days under optimal conditions in soil, eggs embryonate and contain an infections L1 larva. Infection occurs when these embryonated eggs are ingested in food, water, and fomites contained with soil. In the small intestine, the eggs hatch and the larvae migrate to the large intestine (especially the colon and caecum) where they burrow into the intestinal mucosa and molt to become adults. Mated females begin to release eggs 60–70 days post infection (Xie et al., 2018).

Pathogenesis, clinical presentation, and treatment

The pathology and clinical manifestations associated with trichuriasis are primarily due to the localized inflammatory response and blood loss from the adult worms embedded in the colonic mucosa (Else et al., 2020). The extent of tissue damage and symptomatology is strongly linked with the worm burden. Most infected individuals have a low worm burden (<15) and have mild symptoms. In contrast, heavy infection (≥ 800 worms) is associated with clinically-significant colitis and iron deficiency anemia, and patients are likely to have diarrhea (which may be bloody), malnutrition, and abdominal pain (Else et al., 2020). Young children may present with growth retardation and failure to thrive. The most severe manifestation of infection is massive infantile trichuriasis, characterized by chronic mucoid diarrhea, rectal bleeding, iron deficiency anemia, and rectal prolapse (due to mucosal edema and resultant tenesmus) (Else et al., 2020). Treatment is with albendazole, mebendazole, or ivermectin (Medical Letter, 2013).

Diagnosis

Trichuriasis is diagnosed by the detection of eggs in wet mounts of stool and adult worms removed during colonoscopy.

Eggs of *T. trichiura* measure 50–55 μm long by 22–24 μm wide and are barrel-shaped with bipolar hyaline plugs (Fig. 10). They have a thick brown shell and are unembryonated when shed in feces. On rare occasions, eggs of the canine whipworm *T. vulpis* are observed in human stool. The presence of such eggs may reflect spurious passage and not always represent true infection. Eggs of *T. vulpis* are larger, measuring 72–90 μm long by 32–40 μm wide, and are often embryonated in freshly-processed stool specimens (Ash and Orihel, 2007).

Adult worms of *T. trichiura* measure 30–50 mm in length (Fig. 11). They have a long, slender anterior end and a short, thicker posterior end, giving the appearance of a whip, hence the common name. The poster end of the male is often coiled. Adults of *T. trichiura* processed for histopathology will demonstrate traditional characteristics of trichuroid nematodes such as stichocytes around the esophagus and bacillary banding, the former only in the whip-like anterior end (Ash and Orihel, 2007).

***Oesophagostomum* spp. (oesophagostomiasis)**

Oesophagostomiasis is caused by zoonotic nematodes in the genus *Oesophagostomum*. Most human infections have been attributed to *O. bifurcum* in sub-Saharan Africa, but also *O. stephanostomum* in Africa and *O. aculeatum* in Southeast Asia. Infection is initiated by ingestion of L3 larvae on plant material or fomites. The most common clinical presentation is acute abdomen mimicking appendicitis, followed by low-grade fever, anorexia, vomiting, diarrhea, and LRQ pain. Rarely worms will penetrate the intestinal mucosa, causing purulent peritonitis. Diagnosis is made by the finding of eggs in stool. Unfortunately the eggs are very similar to those of hookworm, and separating the two can be difficult in areas of coendemicity (Ghai et al., 2014; Polderman and Blotkamp, 1995).

Trematode infections

***Schistosoma* species (intestinal schistosomiasis, bilharzia)**

Biology and epidemiology

Schistosomiasis, one of the leading causes of morbidity and mortality among parasitic diseases, is caused by “blood flukes” in the genus *Schistosoma*. Six species are usually implicated in human disease: *S. mansoni*, *S. haematobium*, *S. japonicum*, *S. mekongi*, *S. intercalatum*, and *S. guineensis*. *Schistosoma mansoni* is widely distributed in sub-Saharan Africa, as well as in parts of the Middle East, South America (Brazil, Suriname, Venezuela), and the West Indies. *Schistosoma haematobium* is also widely distributed in sub-Saharan Africa and parts of the Middle East, and has been established in Corsica, France where it has hybridized with the

zoonotic *S. bovis*. *Schistosoma intercalatum* is endemic to the Democratic Republic of the Congo and *S. guineensis*, which was historically referred to as the “Guinea strain” of *S. intercalatum*, is distributed in west-central Africa. *Schistosoma japonicum* is distributed in Southeast Asia (primarily in China and the Philippines), while *S. mekongi* is endemic to the Mekong River Valley of Laos and Vietnam (Colley et al., 2014; Gautret et al., 2015; Weerakoon et al., 2015).

Schistosoma species have a complex two-host life cycle involving a vertebrate definitive host and a mollusk intermediate host. Paired adults live *in copula* in the blood vessels of the definitive host. Most human species reside in the mesenteric vessels of the large intestine and rectum except for *S. haematobium*, which resides in the venous plexus of the urinary bladder. *Schistosoma japonicum* and *S. mekongi* can also be found in the superior mesenteric veins draining the small intestine. Ectopic deposition of adults can occur in other sites, such as the liver and lungs. After mating, gravid females leave the male and deposit eggs in the capillaries. Eggs make their way to the lumen of the intestine and are shed into freshwater via the feces. Freshly-shed eggs contain a fully-developed miracidium which hatch in water and infect an appropriate freshwater snail host. In the snail, the parasite undergoes several cycles of asexual reproduction eventually leading to the formation of cercariae. The cercariae leave the snail and swim freely in the water until they come in contact with the skin of a person who is swimming, bathing, or washing laundry in the water. The cercariae penetrate the skin, shed their tails, and become schistosomulae, which are carried via the bloodstream to the lungs or liver where they mature to adults; females will not mature to adulthood unless paired with a male. Paired worms enter the bloodstream and are carried to the mesenteric blood vessels for mating and oviposition (Colley et al., 2014).

Schistosomiasis is considered a neglected tropical disease by the WHO, and there are now global campaigns to prevent and treat this disease in endemic regions. Preventative measures consist of periodic large-scale administration of praziquantel to at-risk individuals (preventative chemotherapy), in addition to access to safe water, snail control, hygiene education, and improved sanitation (WHO, 2020a). While preventative chemotherapy alone will not prevent re-infection in endemic regions, it has been shown to reduce overall disease morbidity and mortality when delivered periodically to at-risk individuals. The WHO estimates that 290.8 million individuals required preventative treatment for this infection in 2018 (WHO, 2020a).

Pathogenesis, clinical presentation, and treatment

Clinical manifestations vary by the stage of infection. Initially, individuals may have a self-limited hypersensitivity response at the site of skin penetration (cercarial dermatitis) in response to dead and dying cercariae (McManus et al., 2018). This is followed by the acute stage of disease in weeks to months after exposure, during which cercariae that successfully mature into schistosomula migrate to the liver, mature, and begin egg deposition. Antigens released from the parasite during this stage trigger a systemic hypersensitivity reactions and immune complex formation. This stage is also known as Katayama syndrome. Clinical manifestations include fever, headache, myalgia, abdominal pain, non-productive cough, eosinophilia, and transient pulmonary infiltrates on radiologic imaging (McManus et al., 2018). Most individuals recover spontaneously after a period of 2–10 weeks. During established active and chronic infection, symptoms are due to the ongoing release of eggs. The eggs secrete glycoproteins which facilitate their passage from the blood vessel through the wall of the colon and into the intestinal lumen. In GI schistosomiasis, the eggs are also swept away by the portal blood supply to the liver, where they induce the formation of eosinophilic granulomas (see Section “Hepato-splenic schistosomiasis”). The tissue granulomas are eventually replaced with fibrous tissue (McManus et al., 2018). Of note, the adult worms are largely able to avoid detection by the host immune response by changing their surface antigens and binding host antigens to their outer tegument.

Intestinal schistosomiasis is characterized by transmural inflammation associated with eggs that are trapped or passing through. Mucosal granulomatous inflammation results in microulcerations, hemorrhage, and pseudopolypoidosis (McManus et al., 2018). This stage is marked by abdominal pain, anorexia, and bloody diarrhea. Treatment is with praziquantel (Medical Letter, 2013).

Diagnosis

Intestinal schistosomiasis is diagnosed by microscopy, including the detection of eggs in wet mounts of stool and histopathologic examination of biopsy specimens, or antibody detection. Antibody detection is especially useful in cases with light infections where egg shedding is below the detection limits of microscopy.

Microscopy

Eggs of *Schistosoma* species are large and conspicuous, but are often shed in small numbers and may not be detected when only one wet mount is examined per stool specimen. In endemic areas, the Kato Katz method and/or microscopic examination of rectal snips is used to enhance diagnosis. The miracidium hatching test can also enhance diagnosis but is rarely used outside of institutional research settings (Weerakoon et al., 2015).

Eggs of all species of *Schistosoma* are large (>50 µm), nonoperculated, possess a lateral or terminal spine, and contain a fully-developed miracidium when shed in feces (Fig. 10). Eggs of *S. mansoni* are 114–175 µm long by 45–70 µm wide and have a conspicuous lateral spine suggestive of a shark fin. Eggs of *S. intercalatum* and *S. guineensis* are 140–240 µm long by 50–85 µm wide, elongate with an equatorial bulge, and have a prominent terminal spine. Eggs of *S. japonicum* are subspherical and measure 70–100 µm long by 55–65 µm wide. They possess a small, inconspicuous lateral spine that is not readily detectable. Eggs of *S. mekongi* are similar to those of *S. japonicum* but slightly smaller, measuring 51–78 µm long by 39–66 µm wide. Eggs of *S. haematobium* are not shed in stool, but may be observed in fecal specimens if contaminated with urine. They are similar to the eggs of *S. intercalatum* and *S. guineensis* and measure 112–170 µm long by 40–70 µm wide but lack the equatorial bulge (Ash and Orihel, 2007).

Eggs, and on rare occasions adults, can be detected in biopsy specimens processed for histopathology. The size and shape of the eggs is often altered due to the angle of cuts, and the spines are often not visible. The presence of large eggs with a mature miracidium in a biopsy specimen is typically pathognomonic for schistosomiasis (Mathison and Pritt, 2018a).

Antibody detection

Antibody detection can be particularly useful in patients with light infections, who have an appropriate travel history and whose stool examinations are negative. Many assays have been developed, including circumoval precipitin test (COPT), indirect hemagglutination (IHA), LFA, IFA, and EIA, and the assays vary in sensitivity and specificity based on the antigen preparation used (crude or purified, adult, egg, or cercarial). Many of these assays have been developed using antigens from *S. mansoni*, which can decrease sensitivity and specificity for other species. For species-specific diagnosis, the most reliable assay is immunoblot (Weerakoon et al., 2015).

There are potential issues to consider regarding antibody detection of schistosomiasis. First, anti-schistosomal antibodies remain for many years post-infection, so a positive antibody test cannot distinguish between past and present infections. Secondly, assays made using crude antigen have a higher rate of cross reactivity to other trematode infections and some nematode infections. In areas of high endemicity, tests should have high specificity to avoid false-positives. However, in areas of nonendemicity, such as travelers returning from endemic areas to the US or Europe, a higher sensitivity assay is preferred for screening, and confirmed with an assay with higher specificity, such as immunoblot (Kinkel et al., 2012; Weerakoon et al., 2015). The CDC in the USA screens with FAST-ELISA using *S. mansoni* adult microsomal antigen (MAMA) and then confirms with immunoblot for the species *S. mansoni*, *S. haematobium*, and *S. japonicum* based on the patient's travel history and clinical presentation. The assays have not been assessed for *S. mekongi*, *S. intercalatum*, and *S. guineensis*, and so sensitivity and specificity might be lower for these three species (<https://www.cdc.gov/dpdx/schistosomiasis/index.html>). While reliable commercially-available assays are available, confirmatory assays such as immunoblot may only be available in endemic areas or large, specialized reference laboratories.

Gastrodiscoides hominis (*Gastrodiscoides* infection)

Gastrodiscoides hominis is a zoonotic trematode infection endemic to Southeast Asia. Hot spots of human infection include India, Pakistan, Myanmar, Vietnam, Philippines, Thailand, and China (Chai et al., 2009). The natural definitive hosts are pigs, although non-human primates, mouse deer, and rodents may serve as reservoir hosts. Adults reside in the lumen of the cecum and colon of the definitive host. Unembryonated eggs are shed into water via the feces. After embryonation, newly-hatched miracidia infect freshwater snails in the genus *Helicorbis*. After cycles of asexual reproduction in the snail host, cercariae leave the snail and encyst as metacercariae on aquatic vegetation, tadpoles, frogs, and crayfish. The definitive host, including humans, becomes infected after eating contaminated plants and animals (Mas-Coma et al., 2006; Chai et al., 2009).

Most infections of *G. hominis* are asymptomatic, and the most common clinical presentation is diarrhea with mucus. Pathologically, there is surface desquamation of the epithelium, and the submucosa and lamina propria are infiltrated with eosinophils, lymphocytes, and plasma cells. Blood vessels are often hyperemic and show thickening of the tunica intima infiltrated with eosinophils and lymphocytes (Mas-Coma et al., 2006). Praziquantel is the drug of choice for *G. hominis* (Mas-Coma et al., 2006).

Gastrodiscoides infection is diagnosed by the detection of eggs in wet mounts of stool or the gross examination of adult flukes removed by endoscopy. Eggs of *G. hominis* are 130–160 µm long by 62–75 µm wide, have an inconspicuous operculum, and are unembryonated in fresh stool specimens. The eggs of *G. hominis* can be very difficult to differentiate from those of *Fasciola* species, *F. buski*, and some echinostomes. Adult flukes 5–14 mm long and are pyriform in shape, with a small, conical anterior end and a large, bulbous posterior portion (Ash and Orihel, 2007).

Parasites of the liver and biliary tree

The parasites that involve the liver and biliary tree encompass both protozoa and helminths (Table 5). Consequences of infection may be life-threatening, such as amebic liver abscess (*Entamoeba histolytica*), hepatic fibrosis (several *Schistosoma* spp.), and cholangiocarcinoma (*Clonorchis sinensis* and *Opisthorchis* spp.).

Protozoan infections

Entamoeba histolytica (hepatic amebiasis)

Hepatic amebiasis is caused by liver infection of the *Entamoeba histolytica*, the only intestinal ameba that causes extraintestinal infection (see Parasites of the Appendix, Large Intestine, and Colon for information on the biology and epidemiology of *E. histolytica* and related amebae). As mentioned previously, the liver is the most common site of extraintestinal *E. histolytica* infection. Other sites include the lungs and brain. Men are 10 times more likely than women to have hepatic amebiasis, although the reasons for this disparity are not fully understood (Wuerz et al., 2012). Trophozoites reach the liver through the portal blood supply and generate a localized inflammatory response resulting in hepatocyte necrosis. The resultant lesion is traditionally referred to as an abscess, although this is a misnomer as neutrophils are not commonly present.

Clinically, patients with hepatic amebiasis present with acute to subacute onset of right upper quadrant pain and fever. Concurrent intestinal symptoms are present in less than 50% of cases. Complications of hepatic amebiasis include rupture into the peritoneal cavity, obstructive jaundice, and bacterial superinfection (Wuerz et al., 2012). Treatment is primarily with metronidazole or tinidazole. An intraluminal agent to clear residual colonic *E. histolytica* cysts (e.g., iodoquinol, paromomycin) is also indicated to prevent recurrent of disease and spread to others. Drainage of the lesion is not generally indicated unless there is a high risk for rupture (e.g., lesion >10 cm in diameter, and/or location in the left lobe of the liver). Diagnosis of hepatic amebiasis is by imaging analysis followed by confirmatory laboratory testing such as antibody detection and molecular analysis. Trophozoites may be detected in permanent-stained smears of liver abscess fluid or in biopsy specimens, but the sensitivity is low and differentiating trophozoites from host WBCs. The nature of the lesional material in hepatic amebiasis is described as resembling “anchovy paste” (Fig. 32).

Ultrasonography and computed topography (CT) scans usually reveal a single abscess measuring on average 4–12 cm; amebic abscesses are more commonly seen in the right lobe of the liver. While amebic abscesses are usually single, multiple abscesses may also be seen (Wuerz et al., 2012).

Antibody detection is the preferred laboratory method for supporting the diagnosis of hepatic amebiasis, especially when corresponding stool examinations are negative (which occurs in 25–50% of cases) (Wuerz et al., 2012). Commercial EIAs tend to have a high sensitivity (greater than 90%) for hepatic and other extraintestinal infections, but cannot reliably differentiate between current and past infection, and so may not a good positive predictor in patients who are from, or spent considerable time in, endemic areas (Ali, 2015).

NAATs can be performed on liver abscess fluid and biopsy specimens. Because *E. histolytica* is the only member of its genus to cause extraintestinal infections, monoplex assays specific for *E. histolytica* can be used over the generally less-sensitive multiplex assays (Ali, 2015; Qvarnstrom et al., 2005). Commercially-available multiplex assays designed for stool specimen should not be used for liver abscess fluid unless thoroughly validated for that specimen type.

Leishmania species (visceral leishmaniasis, kala-azar)

Biology and epidemiology

VL is caused primarily by two species of *Leishmania* in the *donovani*-complex: *L. donovani* and *L. infantum*. *Leishmania donovani* causes anthroponotic infection and endemic areas include India, Nepal, Bangladesh, Sri Lanka, China, Sudan, Ethiopia, and Kenya, with potential hot spots in Bhutan, Chad, Yemen, and Uganda. *Leishmania infantum* causes zoonotic infection with dogs and wild canids as the primary reservoir host and endemic areas of human infection include Mediterranean Europe, North Africa, Southwest Asia, China, and parts of Latin America. *Leishmania archibaldi* (Africa) and *L. chagasi* (Latin America) are believed to be conspecific with *L. donovani* and *L. infantum*, respectively (Ready, 2014). A third species, *L. martiniquensis*, has been implicated as a cause of VL on the Caribbean island of Martinique and in Thailand. *Leishmania siamensis* has also been implicated as a cause of VL in Thailand, but that species is now considered to be conspecific with *L. martiniquensis* (Jariyapan et al., 2018; Pothirat et al., 2014). Leishmaniasis is classified by the WHO as a NTD, and is estimated to cause disease in 50,000–90,000 individuals each year (WHO, 2020a). VL is also recognized as an important opportunistic infection associated with human immunodeficiency virus (HIV). HIV increases the risk of developing active VL, whereas VL accelerates HIV replication; thus coinfection has important clinical and prognostic implications (WHO, 2020c).

The life cycle of *Leishmania* species was covered earlier (Parasites of the Oral Cavity, above).

Fig. 32 Hepatic amebiasis, showing an incised liver lesion (right) and fluid resembling “anchovy paste” (left) that had been extracted from the lesion. Image courtesy of the U.S. Centers for Disease Prevention and Control Public Health Image Library.

Pathogenesis, clinical presentation, and treatment

Visceral leishmaniasis is the most severe form of infection, and active disease nearly always fatal within 2 years if untreated (Burza et al., 2018). The clinical manifestations are due to the infiltration of macrophages carrying amastigotes into the spleen, liver and bone marrow, and include persistent fever, hepatosplenomegaly, pancytopenia, weight loss, and wasting. Non-protective hypergammaglobulinemia is common. Skin hyperpigmentation is seen in the Indian subcontinent resulting in the name, *kala-azar*, meaning black fever. Death is usually a consequence of bone marrow involvement with severe anemia, and leukopenia resulting in opportunistic infections including secondary bacterial infections (Burza et al., 2018). Treatment for VL requires systemic therapy, often with parenteral antimonial drugs (e.g., sodium stibogluconate) or liposomal amphotericin B (Burza et al., 2018; Medical Letter, 2013). Oral miltefosine and parenteral paromomycin may also be used, alone, or in combination with other agents to reduce the likelihood of parasite resistance forming. Patients with HIV co-infection require longer treatment and higher doses, and are at increased risk of relapse (Burza et al., 2018).

Diagnosis

VL is traditionally diagnosed by antibody detection, but can also be diagnosed by microscopy (presence of amastigotes in tissue aspirates and biopsy specimens), culture, isoenzyme analysis, and NAATs. In some larger reference laboratories, NAATs have replaced isoenzyme analysis. It is recommended that more than one method be used to enhance the likelihood of a positive result (Aronson et al., 2016).

Antibody detection

Several serologic assays have been developed for the diagnosis of VL and their sensitivity and specificity varies based on assay type, antigens used, and host factors. Assays include direct agglutination test (DAT), gel diffusion, complement fixation, IHA, IFA, EIA, and LFA (Lockwood and Sundar, 2006; Sundar and Rai, 2002). IgG to *Leishmania* persists for years, so antibody detection should not be used to assess response to treatment and cannot necessarily differentiate present and past infections. The potential for false-negative results can be high in immunocompromised patients and cross reactivity to *Trypanosoma cruzi* can also occur (Aronson et al., 2016).

Dipstick (LFA) assays targeting the rK39 antigen of *L. infantum* shows high specificity and sensitivity. When compared with the CDC's IFA, the Kalazar Detect™ Rapid Test (InBios, Seattle, Washington) shows 98% agreement with 90% sensitivity and 100% specificity (Welch et al., 2008). This assay is FDA-cleared for in vitro diagnostic use in the US.

Microscopy

Tissue aspirates and biopsy specimens can be collected for microscopic analysis, as well as for culture as a prelude to molecular analysis. When VL is suspected, bone marrow is the specimen of choice, but liver, lymph nodes, and whole blood (buffy coat) are also adequate specimens (Aronson et al., 2016).

Aspirates can be stained with Giemsa and examined for the presence of amastigotes. Amastigotes of all *Leishmania* species are morphologically similar to one another, and technically are morphologically indistinguishable from those of *T. cruzi*. Amastigotes are ovoid, measuring 1–5 µm long by 1–2 µm wide and possess a large nucleus and a small rod-like kinetoplast (Fig. 3); (Ash and Orihel, 2007).

Amastigotes can be more challenging to detect in biopsy specimens processed for histopathology due to the angle of the cuts and possible shrinkage during processing. The nucleus is often visible, but the kinetoplast may be more difficult to discern. Promastigotes are not naturally found in clinical specimens but may be observed if there is a substantial delay in processing (Mathison and Pritt, 2018a).

NAATs

In recent years, NAATs have started to replace the traditional diagnostic method of isoenzyme analysis, which is labor intensive and time consuming as it is performed on positive culture isolates which can take a week or more to become detectable (De Almeida et al., 2011). NAATs can also be more useful in immunocompromised patients who are less-likely to have detectable IgG and thus have negative serology results (Sundar and Singh, 2018). NAATs for the detection of VL are likely only to be available in large reference labs in nonendemic areas or reference and academic institutions in endemic areas. Unlike for CL or MCL, where there are many more species implicated in human disease, many PCR assays for VL allow for species-level identification. In the US, the CDC uses a PCR targeting rRNA internal transcriber spacer 2 (ITS2) subunit followed by sequencing analysis for detection and specification of *Leishmania* spp. (De Almeida et al., 2011). LAMP assays also show promise for sensitive, specific, and rapid molecular diagnosis of VL (Sundar and Singh, 2018).

Nematode infections

Capillaria hepatica (hepatic capillariasis)

Biology and epidemiology

Hepatic capillariasis is a relatively rare zoonotic disease caused by the trichuroid nematode *Capillaria hepatica*. The parasite occurs nearly worldwide, with sporadic human cases reported from several countries (Li et al., 2010).

Capillaria hepatica has an unusual one-host life cycle. The natural hosts are rodents, but many mammals, including humans, can serve as adequate hosts. Parasite maturation, mating, and oviposition all take place in the liver parenchyma of the host. Mated females lay eggs that are sequestered in the liver and are not shed into the environment by the host. In order for the eggs to embryonate, they must be released into the environment and come in contact with moist soil, usually by one of two means: (1) death and decomposition of the host, or (2) spurious passage into the environment after the host is eaten by a predator. Once in the soil, the eggs embryonate slowly over a period of about 1.5–6.0 months under optimal conditions and contain an infectious L1 larva. Embryonated eggs are ingested by a new host on food or fomites contaminated with soil; children with pica are at an increased risk of infection. Eggs hatch in the cecum, penetrate the intestinal mucosa, and travel to the portal system where they settle in the liver parenchyma. Once in the liver, L1 larvae molt four times to become adults. Gravid females lay eggs over a period of about 30 days, after which they die (Aghdam et al., 2015; Rocha et al., 2015).

Pathogenesis, clinical presentation, and treatment

The presence of *Capillaria hepatica* developing larvae, adults, and eggs invoke a necrotizing, eosinophilic granulomatous inflammatory response in the liver parenchyma (Li et al., 2010). The worms will eventually die calcify, and the lesions resolve by septal fibrosis. A 2019 report of 16 patients with hepatic capillariasis revealed that eosinophilia, leukocytosis, and sustained fever was the most common findings of infection, being found in 100%, 93.75%, and 56.25% of cases, respectively (Wang et al., 2019). Other signs, symptoms and laboratory findings included elevated hepatic enzymes (60%), abdominal pain (37.5%), pulmonary manifestations (37.5%; e.g., cough and wheezing), and watery diarrhea (25%). Patients have been successfully treated using albendazole or pyrantel tartrate and corticosteroids (Li et al., 2010; Wang et al., 2019; Medical Letter, 2013).

Diagnosis

Hepatic capillariasis is diagnosed by the finding of eggs, and sometimes adult worms, in liver biopsy specimens processed for histopathology. Because of the unique life cycle of the parasite, eggs detected in wet mounts of stool represent spurious passage (i.e., following ingestion of infected liver), and follow-up specimens should be collected and examined to rule-out true infection.

Eggs of *C. hepatica* measure 48–66 µm long by 28–36 µm wide, possess a thick, striated, two-layered shell and bipolar plugs, similar to those of *C. philippinensis* (Fig. 10), but with thicker shell and more ovoid shape. Eggs in biopsy specimens are unembryonated. Adults observed in biopsy specimens will have typical trichuroid features in cross-section, including bacillary bands, stichocytes, and a single reproductive tube (Meyers et al., 2000).

Toxocara canis, *T. cati* (visceral larval migrans, toxocariasis)

Biology and epidemiology

Visceral larval migrans (VLM) is a zoonotic disease caused by ascarid nematodes that in their natural life cycle parasitize carnivorous mammals. VLM and ocular larval migrans (OLM) are predominately caused by *Toxocara canis* and *T. cati* (toxocariasis), cosmopolitan parasites of dogs and cats (Despommier, 2003). VLM can also be caused by the raccoon parasite *Baylisascaris procyonis* (baylisascariasis), however that species has a predilection for the CNS where it causes neural larval migrans (NLM) (Gavin et al., 2005).

In their natural life cycle, adults of *T. canis* and *T. cati* live in the small intestine of dogs and cats, respectively (although both species can infect either host). Unembryonated eggs are shed into the environment via the feces, and in 1–4 weeks under optimal conditions in soil, they mature to contain an infectious L3 larva. New dog and cat hosts become infected after the ingestion of fully-embryonated in contaminated soil. In the small intestine, the eggs hatch and the L3 larvae penetrate the gut wall, migrate through the lungs to the bronchial tree. After a short time in the lungs, the L3 larvae are coughed up and swallowed and mature to adulthood in the small intestine. Dogs and cats can also become infected by eating paratenic hosts harboring eggs, such as earthworms, or harboring L3 larvae, such as rodents and birds. Usually younger dogs and cats are more likely to acquire patent infections. When older animals become infected, the larvae usually become arrested in tissues. In pregnant dogs and cats, these arrested larvae can become reactivated during gestation and can be transferred to their fetuses transplacentally. In cats, *T. cati* can also be transferred to nursing kittens via transmammary route (Despommier, 2003). Thus kittens and puppies may be born infected, or acquire infection during nursing.

Humans become infected after the incidental ingestion of embryonated eggs in food and fomites contaminated with soil. Young children are most likely to become infected, given their close exposure to soil. In particular, children with pica are at higher risk. Egg shedding is highest in puppies and kittens and households with the greatest risk of environmental contamination are those that have adopted feral animals or animals that have had prolonged exposure to outdoor environments. Once a yard or other environment is contaminated with eggs control can be difficult, and under optimal conditions, eggs can remain viable in soil for months or years (Despommier, 2003).

Pathogenesis, clinical presentation, and treatment

The presence of dead and dying larvae within host tissues elicits an immediate- and delayed-type hypersensitivity response, resulting in the formation of necrotizing, eosinophilic granulomas (Despommier, 2003). The extent of host damage and clinical presentation is largely dependent on the burden of infection and the tissues that have been invaded. Eye involvement can lead to impaired sight, and even blindness in some cases. Some cases had been previously misdiagnosed as retinoblastoma, resulting in extreme treatment measures such as enucleation. Fortunately, this misdiagnosis is uncommon today (Despommier, 2003). Visceral larva migrans

typically presents with fever, hepatosplenomegaly, asthma-like respiratory symptoms, and high levels of eosinophilia (e.g., approaching 70%). Hypergammaglobulinemia is also commonly present (Despommier, 2003). Albendazole is the preferred anti-helminthic drug for treating toxocariasis, and may be administered in conjunction with corticosteroids to decrease harmful inflammation and suppress allergic manifestations (Despommier, 2003; Medical Letter, 2013).

Diagnosis

VLM is diagnosed primarily by clinical presentation and confirmed by antibody detection. L3 larvae may be observed in liver biopsy specimens, however biopsies are rarely collected when VLM is suspected.

Antibody detection

Antibody detection for VLM is primarily performed by EIA. These assays can usually detect both *T. canis* and *T. cati*, but cannot distinguish between the two. *Toxocara* serology will also commonly detect antibodies to *B. procyonis*. Arrested larvae in human tissues usually survive for months to years, continuously releasing antigens that keep the immune response stimulated. As such, antibodies may persist for years. After antihelminthic treatment, IgG levels have been shown to decline but may remain detectable for 4–5 years (Wilkins, 2014).

Historically, EIAs were developed using antigens extracted from embryonated eggs or L3 larvae cultured in vitro. The development of EIAs using *Toxocara* excretory-secretory (TES) antigens showed improved sensitivity and specificity. Assays may detect either IgG or IgE, but it is debatable which offers better specificity (Wilkins, 2014).

Microscopy

L3 larvae of *Toxocara* spp. in liver biopsy specimens are 290–350 μm long and 15–21 μm in diameter (Fig. 33). They possess typical features of ascarid larvae such as prominent excretory canals, few muscle cells per quadrant, and prominent lateral alae. As they remain in their larval state, reproductive structures are not present. Larvae of *B. procyonis* share similar features but are slightly larger, at upwards of 1.4 mm long and 62 μm in diameter (Mathison and Pritt, 2018a). While larvae are only rarely seen in biopsies, evidence of the host immune response (e.g., eosinophilic granulomas and abscesses) is commonly appreciated.

Trematode infections

Schistosoma species (hepatosplenic schistosomiasis)

Biology and epidemiology

Hepatosplenic schistosomiasis is caused by the same species that cause intestinal schistosomiasis. The biology and epidemiology of these trematodes are discussed previously (Parasites of the Appendix, Large Intestine, and Anus Above).

Fig. 33 Longitudinal section of a *Toxocara* sp. larva (arrow, inset) in a liver biopsy, associated with eosinophilic abscesses (H&E, 200 $\times$; inset 1000 $\times$). From Mathison BA and Pritt BS (2018) Chapter 5: Parasitic Diseases. In: *Atlas of Fundamental Infectious Diseases Histopathology: A Guide for Daily Practice*. Pritt BS (ed.). Pathologists: Northfield, IL: College of American.

Pathogenesis, clinical presentation, and treatment

As mentioned above, clinical manifestations vary by the stage of infection. This section will only address hepatic manifestations that occur during established active and chronic infection, when eggs are swept to the liver via the portal blood supply and induce the formation of eosinophilic granulomas in the pre-sinusoidal periportal tissues. This initially results in substantial enlargement of the liver and spleen (McManus et al., 2018) (Fig. 34). The tissue granulomas are eventually replaced with fibrous tissue and the size of the liver shrinks. Collagen is deposited around branches of the portal vein, leading to a distinct entity called Symmer's pipestem (or clay pipe) fibrosis, named due to the appearance of the thickened portal tracts in gross specimens, which are thought to resemble a clay pipe stem in cross-section. Of note, there is usually no hepatic parenchymal damage in hepatic schistosomiasis, and cirrhosis does not occur. Fibrosis is irreversible, and may lead to occlusion of small branches of the portal vein, with resultant portal hypertension and associated sequelae (e.g., esophageal varices, ascites). Since there is no damage to the hepatic parenchyma, liver enzymes are within normal ranges (McManus et al., 2018). Treatment is with praziquantel. Unfortunately, sequelae associated with fibrosis may be irreversible.

Diagnosis

See the section above on intestinal schistosomiasis. Eggs may be seen in liver biopsies in association with a granulomatous or fibrous host cell response (Fig. 35).

Fasciola hepatica and *F. gigantica* (fascioliasis)

Biology and epidemiology

Fascioliasis is a zoonotic trematode infection caused by *Fasciola hepatica* and *F. gigantica*. *Fasciola hepatica* has a worldwide distribution where cattle, sheep, and other ruminants are farmed. Hot spots of endemicity for human disease include the Bolivian Altiplano, Ecuador, Peru, Cuba, Portugal, Spain, Turkey, the Nile Delta, Iran, and Vietnam (Tolan, 2011). The WHO estimates 2.4 million people are infected in more than 70 countries (https://www.who.int/foodborne_trematode_infections/fascioliasis/en/). *Fasciola gigantica* is more geographically restricted, being endemic to tropical Africa, the Middle East, and Southeast Asia, in areas where *F. hepatica* also occurs (Tolan, 2011).

Fasciola spp. have a complex two-host life cycle. Adults reside in the biliary ducts of the mammalian definitive host. Natural hosts for *Fasciola* spp. are primarily herbivorous ruminants, such as sheep, cattle, goats, deer, and camels. Unembryonated eggs are discharged into the biliary ducts and are passed into the environment in feces. In freshwater, eggs embryonate over a period of approximately 2 weeks. Embryonated eggs hatch, releasing miracidia that infect an appropriate snail intermediate host. Snail hosts for *Fasciola* are members of the family Lymnaeidae, including *Galba*, *Lymnaea*, and *Pseudosuccinea*. In the snail host, the parasite undergoes several asexual cycles resulting in the formation of cercariae. Cercariae leave the snail host and encyst as metacercariae on aquatic vegetation such as watercress. The definitive host becomes infected after ingesting contaminated aquatic plants or drinking water contaminated with liberated metacercariae. Metacercariae excyst in the duodenum, penetrate the intestinal wall, and migrate to the biliary ducts where they mature to adults. Eggs are usually shed in stool 8–2 weeks post infection (Tolan, 2011).

Fig. 34 Young Puerto Rican boy with a visibly-distended abdomen due to hepatosplenomegaly caused by schistosomiasis. Image courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

Fig. 35 *Schistosoma mansoni* eggs within a granuloma (H&E, 400 $\times$). Note the presence of a characteristic lateral spine (arrow) which is defining for this species, as well as the nuclei of the miracidium within the egg. It is not always possible to identify spines on eggs in tissue, and care must be taken not to overinterpret egg shell irregularities that occur during tissue processing as true spines.

Pathogenesis, clinical presentation, and treatment

The pathology and clinical manifestations of fascioliasis are due to the migration of the maturing fluke through Glisson's capsule of the liver and the hepatic parenchyma, and the eventual presence of the adults within the biliary tree (Saba et al., 2004; Tolan, 2011). More than 50% of infections are thought to be asymptomatic. When present, manifestations of the liver migration stage commonly include fever, myalgias, arthralgias, eosinophilia and leukocytosis. Urticaria, asthma-like respiratory symptoms, weight loss and headache may also be seen (Tolan, 2011). Later in infection, the presence of the adults in the biliary tract may result in cholelithiasis, ascending cholangitis, pancreatitis, cholelithiasis, biliary cirrhosis, and hepatic fibrosis. Unlike infection with *Clonorchis* and *Opisthorchis*, cholangiocarcinoma is not seen with fascioliasis (Tolan, 2011). Triclabendazole is the treatment of choice. Of note, the drug of choice for other trematode infections, praziquantel, is ineffective in treating fascioliasis (Medical Letter, 2013).

Diagnosis

Fascioliasis is diagnosed primarily by the detection of eggs in wet mounts of stool or by antibody detection. Because eggs are usually be detected in stool until about 8–12 weeks post infection, antibody detection may be used for diagnosing early infection. Occasionally adults may be observed via endoscopic retrograde cholangio-pancreatography (ERCP) or adults and eggs may be observed in biopsy specimens processed for histopathology.

Microscopy

Fascioliasis may be diagnosed microscopically by the detection of eggs in wet mounts of stool, less commonly by the finding of adult flukes via ERCP or biopsy specimens stained for histopathology. Eggs of *F. hepatica* measure 130–150 μm long by 63–90 μm wide (Fig. 10); those of *F. gigantica* are larger at 160–190 μm long by 70–90 μm wide. Eggs of both species have a thick shell, a small, inconspicuous operculum, and are unembryonated when shed in stool. The eggs of *F. hepatica* are morphologically indistinguishable from those of *Fasciolopsis buski*, and can be difficult to separate from other flukes such as *Gastrodiscoides hominis* and the echinostomes. It is therefore common for laboratories to report the finding of characteristic eggs as *Fasciola* spp./*Fasciolopsis buski* eggs (Ash and Orihel, 2007).

It is important to remember that the presence of *Fasciola* eggs in stool might represent spurious passage after the ingestion of infected beef or sheep liver, rather than true infection. Follow-up stool exams on positive patients should be ordered to rule-out spurious passage (Ash and Orihel, 2007). Patients should be instructed not to ingest liver during this follow-up period.

Grossly, adult flukes are large, measuring up to 30 mm long by 13 mm wide. They are flat, leaf-like in shape, and the anterior end is distinctly cone-shaped (Ash and Orihel, 2007). Adults observed in biopsy specimens will have inherent features of trematodes. The tegument will typically have flattened, scale-like spines. Eggs observed in biopsy specimens are large and unembryonated. The only fluke eggs in a liver biopsy specimen what would near *Fasciola* in size are those of *Schistosoma*, which should contain a mature miracidium (Mathison and Pritt, 2018a).

Antibody detection

Antibody detection allows for diagnosis of fascioliasis that can be particularly helpful for diagnosing early or acute infection. Antibodies can be detected as early as 2 weeks post infection, nearly 2–3 months earlier than when eggs are typically observed in stool. Early diagnosis and treatment of fascioliasis can prevent chronic severe liver damage. While sensitivity and specificity of most assays are high, some cross-reactivity with other helminth infections does occur (Sarkari and Khabisi, 2017).

The most common platform for immunodiagnosis of fascioliasis is EIA. There are some commercially-available assays, including the DRG Fasciola IgG ELISA (DRG International, Springfield, New Jersey) which has FDA and CE approval. Assays are usually developed using excretory-secretory antigens. The most-studied antigens used in development of assays include the 27 kDa and cathepsin L1 (CL1) antigens. The saposin-like protein 2 (SLP-2) also demonstrated high sensitivity and specificity. Most assays are developed using antigens from *F. hepatica* and may express varying degrees of specificity for *F. gigantica*. Assays that can detect both cannot differentiate between the two species, but species-level identification is not needed for clinical management (Sarkari and Khabisi, 2017). Researchers at the CDC developed immunoblot and Luminex-based assays using the glutathione S-transferase recombinant antigen GST-FhSAP2 for the immunodiagnosis of fascioliasis. Both assays exhibited relatively high sensitivity and specificity, but there was some cross-reactivity with other helminth infections. The immunoblot assay showed some cross-reactivity to hookworm and toxocariasis with total IgG and hookworm with IgG4. The Luminex assay some cross-reactivity to schistosomiasis and toxocariasis with total IgG and some cross-reactivity to hookworm with IgG4 (Shin et al., 2016).

Clonorchis sinensis, Opisthorchis viverrini, O. felinus (clonorchiasis, opisthorchiasis)

Biology and epidemiology

Clonorchis sinensis, *Opisthorchis viverrini*, and *O. felinus* are often referred to as the ‘small liver flukes.’ *Clonorchis sinensis* (the ‘Chinese liver fluke’) is endemic to East Asia, with hot spots of human infection in Korea, China, Taiwan, and Vietnam (Qian et al., 2012). *Opisthorchis viverrini* is endemic to Southeast Asia, with hot spots of human infection in Thailand, Laos, Vietnam, and Cambodia (Kaewpitoon et al., 2008). *Opisthorchis felinus* is endemic to Eastern Europe, Central Asia, and Russia (Pakharukova and Mordvinov, 2016). In Canada and the northern USA, can humans rarely become infected with another small hepatic trematode, *Metorchis conjunctus* (Behr et al., 1998; Maclean et al., 1996).

All opisthorchid trematodes have a similar three-host life cycle. Adults reside in the biliary ducts of the definitive hosts. Embryonated eggs containing a fully-developed miracidium are discharged from the biliary ducts and passed in stool. In fresh water, the eggs are ingested by a suitable freshwater snail host. In the snail host, the miracidium undergoes cycles of asexual reproduction resulting in the formation of cercariae. The cercariae leave the snail host and infect freshwater fish. Over 100 species of fish have been documented as suitable hosts. In the flesh of the fish, the cercariae encyst as metacercariae. The definitive host, including humans, becomes infected after eating raw or undercooked fish harboring metacercariae. The metacercariae excyst in the duodenum and ascend the biliary tree via the ampulla of Vater. Maturation to adults takes approximately 1 month (Kaewpitoon et al., 2008).

Pathogenesis, clinical presentation, and treatment

Most of the pathology associated with *Clonorchis sinensis* and *Opisthorchis* spp. infection is due to the presence of the adult flukes in the bile ducts (Kaewpitoon et al., 2008). The extent of symptoms depends on the parasite burden, duration of infection, and host factors. Many infections are asymptomatic. When present, common manifestations include cholangitis, cholecystitis, cholelithiasis, hepatomegaly, and obstructive jaundice. There is also a strong association of long-standing infection with cholangiocarcinoma. Pathologic findings include bile duct dilation, periductal fibrosis and inflammation, marked biliary epithelial hyperplasia, and biliary metaplasia (Choi et al., 2004). The etiology of cholangiocarcinoma is thought to be multifactorial, and include mechanical damage caused by the flukes within the bile ducts (e.g., from their suckers and metabolic by-products), parasite secretions, and perhaps most importantly, epithelial damage caused by the host immune response (Choi et al., 2004; Kaewpitoon et al., 2008). The patient’s genetic makeup and exposure to environmental carcinogens (e.g. N-nitroso compounds in food) may also contribute to progression to cholangiocarcinoma (Kaewpitoon et al., 2008).

Signs and symptoms include malaise, fever, abdominal discomfort, distension, anorexia, weight loss, and diarrhea. Testing commonly reveals a peripheral eosinophilia and hyperbilirubinemia. Late stage infection may be associated with hepatosplenomegaly, portal hypertension and ascites (Choi et al., 2004). As with most other trematode infections, the treatment of choice is praziquantel (Medical Letter, 2013).

Diagnosis

The diagnosis of opisthorchiasis and clonorchiasis is primarily made by the finding of eggs in concentrated wet mounts of stool, although antibody detection and NAATs may be available in endemic areas (Kaewpitoon et al., 2008).

Eggs of the opisthorchid trematodes are all very similar in size and shape. Eggs of *C. sinensis* are 27–35 µm long by 12–19 µm wide, have prominent opercular shoulders, an abopercular knob, and contain a miracidium with passed in feces (Fig. 10). Eggs of *Opisthorchis* spp. are smaller at 19–29 µm long by 12–17 µm wide. Despite the smaller size, there is sufficient overlap that a genus-level identification may be challenging. It is not uncommon for labs to issue a combined report (e.g., *Clonorchis sinensis*/*Opisthorchis* spp. eggs) (Ash and Orihel, 2007). Eggs of *M. conjunctus* are 28.5 µm long by 15.6 µm wide on average (Maclean et al., 1996).

Dicrocoelium dendriticum, D. hospes (dicrocoeliasis)

Dicrocoeliasis is a rare zoonotic disease caused by liver flukes in the genus *Dicrocoelium*. Most true human infections are caused by *D. dendriticum*, which occurs in North America, Asia, Europe, northern Africa, and the Middle East. *Dicrocoelium hospes* causes rare human disease in West Africa (Cengiz et al., 2010; Odei, 1966). Like other trematodes, *Dicrocoelium* spp. have a complex multi-host life cycle. Definitive hosts are typically ruminants, including cattle, sheep, and goats. The first intermediate hosts are terrestrial snails. The second intermediate hosts and source of infection for the definitive hosts are ants (Cengiz et al., 2010).

Infection is often asymptomatic. When present, patients with dicrocoeliasis may present with abdominal distention, RUQ pain, diarrhea, constipation, and weight loss. Peripheral eosinophilia and anemia are common laboratory findings. Heavy infections may result in cholecystitis and liver abscesses (Cengiz et al., 2010). Successful treatment has been reported using praziquantel or triclabendazole (Cengiz et al., 2010; Schweiger and Kuhn, 2008).

Diagnosis of dicrocoeliasis is made by the finding of eggs in concentrated wet mounts of stool. Humans can spuriously pass *Dicrocoelium* eggs after ingesting infected animal livers, so multiple specimens should be collected and examined to rule-out or confirm true infection (Cengiz et al., 2010). Eggs of *D. dendriticum* measure 38–45 µm long by 22–30 µm wide, have a thick shell, an inconspicuous operculum, lack an abopercular knob, and contain a fully-developed miracidium when shed in feces (Ash and Orihel, 2007).

Cestode infections

Echinococcus granulosus-complex (cystic echinococcosis)

Biology and epidemiology

Cystic echinococcosis (CE) is a zoonotic cestode infections caused by members of the genus *Echinococcus*, primarily by species in the *granulosus*-complex. There is currently not a taxonomic standard for the number of valid species in the complex. Some systems recognize one species, *E. granulosus*, with numerous genotypes or strains, while others recognize multiple species. A recent study on the molecular epidemiology of members of the *granulosus*-complex recognizes three species that have been implicated in human disease: *E. granulosus* (genotypes G1-G3, the sheep-buffalo strains), *E. canadensis* (genotypes G6-G8, G10, pig, camel, and cervid strains), and *E. ortleppi* (genotype G5, cattle strain). Most of these species have wide distributions in North America, Europe, Asia, and the Middle East. In South America, two additional species cause neotropical cystic (a.k.a. polycystic) echinococcosis, *E. oligarthra* and *E. vogeli* (Romig et al., 2015). The WHO has classified echinococcosis as an NTD and estimates that more than 1 million people are infected by *Echinococcus* species at any one time (WHO, 2020a).

All species have a similar life cycle that cycles between a carnivore definitive host and an herbivore intermediate host. Most species use dogs and wild canids as definitive hosts (*E. oligarthra* uses wild felids as a definitive host). Adult cestodes reside in the small intestine of the definitive host. Eggs are shed via the feces and contaminate the surrounding environment. The natural intermediate host becomes infected after the ingestion of infectious eggs while grazing. The eggs hatch in the intestine of the intermediate host and the liberated oncosphere is carried via the bloodstream to other organs where it develops into a hydatid cyst (metacestode). Within the primary cyst, daughter cysts and protoscoleces develop (Fig. 36). Each protoscolex has the potential of becoming an adult tapeworm when eaten by a suitable definitive host. A new definitive host becomes infected after eating infected intermediate hosts. Humans serve as an incidental, dead-end intermediate host after the ingestion of tapeworm eggs in food and fomites contaminated with canine feces (Eckert and Deplazes, 2004). In humans, hydatid cysts can localize in many organs, with the liver being the most common site, followed by the lung (Eckert and Deplazes, 2004).

Fig. 36 Echinococcal cyst that has been incised to reveal multiple collapsed daughter cysts within. Courtesy of the U.S. Centers for Disease Control and Prevention Public Health Image Library.

Pathogenesis, clinical presentation, and treatment

The pathogenesis and clinical manifestations vary based on the size of the lesion and location in the host. Cystic echinococcosis begins as a microscopic lesion and slowly grows over time, so that many years may elapse between infection and clinical presentation (Wen et al., 2019). Lesions become clinically relevant when impinge upon neighboring structures. Patients with liver cysts commonly present with abdominal discomfort and decreased appetite. Jaundice may occur with compression of the biliary tree. Cyst leakage or frank rupture can result in life-threatening allergic reactions, ranging from urticaria, fever and peripheral eosinophilia to anaphylactic shock (Wen et al., 2019). Leakage into the surrounding tissue can also result in local dissemination of the parasite. Treatment varies with the type and size of the cyst (see Imaging below) (Wen et al., 2019; Medical Letter, 2013). Of note, it is no longer considered ‘taboo’ to insert a needle in CE lesions, so long as proper precautions for preventing anaphylaxis and dissemination are in place. For cysts that are amenable to drainage via percutaneous aspiration, the preferred treatment is now the PAIR technique (puncture, aspiration, injection and reaspiration), or the modified catheterization technique (MoCAT). These methods use percutaneous drainage in conjunction with injection of a protoscolicidal agent to deflate the cyst and kill the inner reproductively-active germinal layer without the need for surgery. The MoCAT represents an improvement upon the PAIR technique in that parasitic membranes are aspirated in addition to the cyst contents. The antihelminthic drug, albendazole, is administered in conjunction with PAIR and MoCAT therapy. For more complex cysts, surgical removal is required, in addition to albendazole.

Diagnosis

The diagnosis of CE is usually initially performed by imaging analysis followed up with serologic testing (antibody detection) for confirmation. Echinococcosis can also be diagnosed microscopically by the finding of cysts in biopsy specimens or liberated protoscoleces in aspirate specimens.

Imaging

Hydatid cysts are classified into four categories based on their radiologic findings. Type I cysts are simple cysts with no visible internal structures; they are believed to represent early and active cysts. On CT, Type I cysts appear as well-defined water-attenuated lesions. Magnetic resonance imaging (MRI) shows hypointensity on T1-weighted images and hyperintense lesions on T2-weighted images. Type II cysts are cysts that have daughter cysts within the primary cyst. On imaging analysis, Type II cysts usually appear with a rosette or honeycomb pattern caused by the daughter cysts. Type III cysts are calcified cysts. On CT, Type III cysts appear as round hyperattenuating areas while on MRI they appear as hypointense areas. Type IV cysts are classified as ‘complicated cysts’ due to an abnormal size and profound mass effect on neighboring organs or because they have ruptured. In the case of ruptured cysts, fissures can be seen in the cyst wall on both CT and MRI (Marrone et al., 2012; Polat and Atamanalp, 2009).

Antibody Detection

Many assays have been developed for antibody detection of *Echinococcus* spp., including EIA, IFA, immunochromatographic card tests (ICTs), immunoelectrophoresis, and immunoblot. The sensitivity and specificity of these assays varies from platform to platform. Generally, assays such as EIA and IFA are good for screening, but assays with higher specificity, such as immunoblot, are better for confirmation (Zhang et al., 2012). Patients with single, well walled-off cysts might not have a measurable antibody response, so a negative result does not rule-out disease. Likewise, false positives can occur in patients with other helminth infections, tumors, or autoimmune disorders (Chen et al., 2014). In particular, a high degree of cross-reactivity has been noted with cysticercosis.

Microscopy

In liver biopsy specimens, a hydatid cyst appears as a well-defined cyst surrounded by a thick fibrous wall of host origin. The outer layer is thick, acellular, and elastic. It often appears to be made of several smaller layers (‘laminated layer’). The inner cyst layer is nucleated and serves as a germinal base for daughter cells which contain multiple protoscoleces. An individual protoscolex are invaginated and contain hooklets and many calcareous corpuscles which are a hallmark of cestode anatomy (Fig. 37).

The presence of multiple protoscoleces rules-out cysticercosis caused by *Taenia solium*, which possesses only one protoscolex per cyst. In cases of coenurosis (a zoonotic disease caused by canine parasites in the genus *Taenia*), multiple protoscoleces can also occur. However, in cases of coenurosis, there are no daughter cysts within the primary cyst (Mathison and Pritt, 2018a). Wet mount aspirates of cysts may show liberated protoscoleces and freed hooklets and calcareous corpuscles from disintegrated protoscoleces (‘hydatid sand’) (Ash and Orihel, 2007).

Echinococcus multilocularis (alveolar echinococcosis)

Biology and epidemiology

Alveolar echinococcosis (AE) is a zoonotic cestode infection caused by *Echinococcus multilocularis*. The disease occurs in the Northern Hemisphere, including Canada and northern USA, Europe, Russia, and Central Asia. The life cycle is similar to members of the *E. granulosus*-complex (above), with foxes serving as natural definitive hosts and rodents serving as intermediate hosts. When humans become infected with *E. multilocularis* after the ingestion of eggs in food or fomites contaminated with canid feces; the most common site of infection is the liver. However, the destructive nature of the alveolar cyst can lead to infection of neighboring organs and the CNS (Wen et al., 2019).

Fig. 37 Protoscolexes aspirated from a case of cystic echinococcosis. Note the refractile hooklets (arrows) within each protoscolex (400 ×). From Mathison BA and Pritt BS (2018) Chapter 5: Parasitic Diseases. In: *Atlas of Fundamental Infectious Diseases Histopathology: A Guide for Daily Practice*. Pritt BS (ed.). Pathologists: Northfield, IL: College of American.

Pathogenesis, clinical presentation, and treatment

Unlike the single cystic lesion of cystic echinococcosis, AE results in a proliferation of infiltrating cysts that invade neighboring structures and organs (Fig. 38) (Wen et al., 2019). The disease is usually fatal if not treated. The preferred treatment, when possible, is complete resection of the lesions, in conjunction with prolonged albendazole therapy. Life-long suppression with albendazole may be required when complete surgical resection is not possible (Wen et al., 2019; Medical Letter, 2013).

Diagnosis

The diagnosis of alveolar echinococcosis is made initially by imaging analysis followed by serology or microscopy (histopathology) for confirmatory diagnosis.

Imaging analysis

On ultrasonography, cysts of *E. multilocularis* appear as mass lesions with a mixed heterogeneous echogenic pattern with irregular contours, cystic necrotic areas, and calcified foci. On CT, cysts appear tumor-like masses with irregular borders, variable internal structures, and random calcified foci. MRI can be helpful for extra-abdominal cysts, but is not as sensitive for detecting calcifications

Fig. 38 Alveolar echinococcosis in a cotton rat (*Sigmodon* sp.) in which the liver and other abdominal organs have been infiltrated by cysts of varying sizes. Courtesy of the U.S. Centers for Disease Control and Prevention.

seen with CT. The typical finding on MRI is a mass lesion with infiltrative characteristics having irregular borders. There is usually hypointensity or isointensity on T1-weighted images and hypotensity, isotensity, or hypertensity on T2-weighted images (Bulakçı et al., 2016).

Antibody detection

Antibody detection for the diagnosis of AE is usually made by EIA targeting excretory-secretory antigens derived from intact cysts. The Em2^{plus} EIA (Bordier, Crissier, Switzerland) had been used in Europe extensively for the diagnosis of AE with sensitivity and specificity approaching 90% (Wen et al., 2019).

Microscopy

On histopath examination, cysts of *E. multilocularis* grow in an invasive fashion as cysts arise indefinitely from the germinal layer. Laminated and germinal layers are convoluted and folded on themselves, scattered throughout the host tissue. Protoscoleces are absent, as are calcareous corpuscles, usually (Mathison and Pritt, 2018a).

Infections of the eyelids

The eyelid shields the anterior surface of the eye from the environment and injury; it is a physical barrier and contains a row of eyelashes that protect the eye from dust particles, foreign bodies and perspiration. The eyelids have a vascular supply, lymphoid tissue and lymphatic drainage as well as innervation to a central muscle. An imbalance of these local and systemic defenses can cause bacterial infections of the eyelid.

Bacterial blepharitis

Anterior bacterial blepharitis is typically caused by staphylococcal infection and affects the base of the eyelashes producing inflammation of the lid margin. Other causative organisms include *Propionibacterium acnes* and *Corynebacterium* species (Jackson, 2008). The disease can occur in all ages, ethnicities, and gender. However, it is more common in adults older than 50 years of age (Pflugfelder et al., 2014). Ocular symptoms include itching, burning, gritty, red eyes, dry or watery eyes, blurred vision, foreign body sensation, and crusting of the eyelids. Symptoms are often worse in the morning (Fig. 1). Patients typically exhibit eyelash loss and/or misdirection, a feature that is rarely seen with other types of blepharitis. Diagnosis is based on patients' signs and symptoms, and bacterial cultures can be performed to confirm bacterial infection.

Treatment consists of a combination of lid hygiene, warm compresses (10 mins, two to four times a day) and topical antibiotics. Topical ointments such as erythromycin or bacitracin applied to the eyelid margin have been shown to provide symptomatic relief and are effective in eradicating bacteria from the eyelid margin (Lindsley et al., 2014). With the increase of antibiotic resistance to *Staphylococcus*, Fusidic acid is a good alternative, as it covers *Staphylococcus epidermidis*, *Staphylococcus aureus* and methicillin-resistant *S. aureus*. Aminoglycosides (e.g., gentamicin or tobramycin) can be used but do not have the same broad coverage against gram-positive bacteria and are more likely to cause toxicity with prolonged use (Jackson, 2008). Fluoroquinolones (e.g., ciprofloxacin and levofloxacin ophthalmic solutions) have shown effectivity in managing bacterial blepharitis, but their long-term use has been discouraged due to the increase in antibiotic resistance (Yactayo-Miranda et al., 2009; Jackson, 2008). Topical vancomycin and azithromycin have also been used to treat blepharitis (Fleischer et al., 1986; Haque et al., 2010). Intermittent topical antibiotic treatment can be repeated using different medications to prevent the development of antibiotic resistant (Preferred Practice Pattern, 2018). Short-term topical corticosteroids (less than 2 weeks) may be beneficial in controlling inflammation in severe cases. The lowest effective topical steroid dose should be employed, and a tapering course administered (Preferred Practice Pattern, 2018).

Fig. 1 Clinical presentation of blepharitis.

Antibiotic-steroid combinations are also available in either ointment or eye drop form and may be suitable for some patients (Jackson, 2008). To prevent blepharitis, good eyelid hygiene and elimination of triggers that exacerbate symptoms such as thorough removal of eye makeup should be performed (Fig. 1).

Preseptal cellulitis

Preseptal cellulitis is an infection of the soft tissues localized anterior to the orbital septum. The condition most commonly affects children and primarily caused by trauma or sinusitis (Hauser and Fogarasi, 2010). The most common causative organisms for preseptal cellulitis are *Staphylococcus*, *Streptococcus* and *Haemophilus*. The infection is usually unilateral and presents with edema and erythema of the peri-orbital skin. Patients may experience eye pain, redness and a tender eyelid whilst maintaining full extraocular movements, without proptosis, and no changes to vision. This is because the extent of the infection is superficial; it does not extend posteriorly into the orbit. Preseptal cellulitis rarely leads to serious complications, however, the infection may extend posteriorly via facial and ophthalmic veins causing orbital cellulitis (Chaudhry et al., 2012). In extreme cases, it can extend further to cause subperiosteal abscess, orbital abscess, intracranial infection or cavernous sinus thrombosis (Baring and Hilmi, 2011).

Diagnosis is based on patient history, clinical features and radiologic findings. Patients with preseptal cellulitis typically will have a history of sinusitis or upper respiratory infection, trauma, or infection or insect bites in a nearby area. Preseptal and orbital cellulitis have similar presentations making the differential diagnosis difficult. It is important to note the patient's temperature (i.e., fever) and ophthalmic complaints as these may indicate orbital cellulitis. In orbital cellulitis there is typically eyelid edema and erythema, diminished visual acuity, proptosis, a relative afferent pupillary defect, reduced color saturation, chemotic conjunctiva and reduced extraocular movements (Basic and Clinical Science Course, 2007). Preseptal cellulitis tends to present with eyelid edema and erythema, but with normal visual acuity, pupil reaction to light, color saturation, conjunctiva and ocular movements. A computerized tomography (CT) scan of the orbits and sinuses can be used to differentiate between the two conditions, as well as depicting the extent of the infection. A CT scan of preseptal cellulitis will show eyelid swelling, no proptosis, no fat stranding of orbital contents, and no involvement of the extraocular muscles (Carlisle and Digiovanni, 2015; Hauser and Fogarasi, 2010).

The mainstay of treatment is broad-spectrum systemic antibiotics with coverage against gram-positive and gram-negative bacteria. Most patients with preseptal cellulitis are managed with oral antibiotics, such as fluoroquinolones or azithromycin. Intravenous antibiotics such as third-generation cephalosporins or ampicillin are recommended for children less than 1 year of age, immunosuppressed patients and those with severe systemic infections (Hauser and Fogarasi, 2010; Ferguson and McNab, 1999). Initial antibiotic therapy should be altered if there is no response to treatment or laboratory cultures indicate otherwise.

Hordeolum

An acute infection of the sebaceous glands of Zeis, usually caused by *S. aureus* is known as a hordeolum (Lindsley et al., 2017). Hordeolum can form on the external eyelid and are commonly referred to as a "stye" and are common in both children and adults. Predisposing risk factors include blepharitis, meibomian gland dysfunction, ocular rosacea, seborrheic dermatitis and diabetes mellitus (McAlinden et al., 2016). It typically presents in the form of focal abscess manifesting as a painful, swollen, edematous and erythematous inflammation of the eyelid (Carlisle and Digiovanni, 2015). It can also occur on the inner eyelid and be mistaken for a chalazion. Diagnosis is based on clinical features. The disorder is usually self-limiting, lasting 1–2 weeks and often resolves on its own via spontaneous rupture. Warm compresses and massage therapy (10 mins four times a day) can assist by softening the granulomatous tissue and facilitating drainage. Persistent or complicated lesions may require antibiotic therapy. Incision and drainage may be required for persistent abscess (McAlinden et al., 2016).

Impetigo

A highly contagious infection of the superficial layers of the epidermis, commonly caused by gram-positive bacteria. It is prevalent in children ages 2–5 years old but can occur at any age (Cole and Gazewood, 2007). Impetigo of the eyelid is usually associated with infections of the face, caused by skin disorders such as eczema, insect bites, poison ivy, and cuts or scrape due to minor trauma, by *S. aureus* or *Streptococcus pyogenes* (May et al., 2019). Diagnosis is typically based on clinical features. The infection starts as a tiny blister, which eventually bursts, leaving multiple lesions. Bacterial cultures can be performed to confirm diagnosis. Impetigo often resolves spontaneously, however, topical or oral antibiotic treatments decrease the duration of the infection and spread of lesions (Smith et al., 2018). Antibiotics prescribed should cover both *S. aureus* and *S. pyogenes*.

Erysipelas

A bacterial skin infection mainly caused by Group A *Streptococcus*. Individuals with obesity, lymphedema, leg ulcers, smokers, diabetes mellitus, and dermatitis are predisposed to erysipelas (Raff and Kroshinsky, 2016). Patients typically experience high fever, chills, fatigue, headaches and vomiting within 48 h of initial infection. Eyelid symptoms include erythematous, swollen, warm, hardened, and enlarged painful skin lesions. Diagnosis is based on clinical features and the patients' medical history. Initial treatment should be with *Streptococcus* susceptible antibiotics. Monotherapy oral penicillin is sufficient for most cases and should be given for 5–10 days (Stevens et al., 2014). For patients' allergic to penicillin, first-generation cephalosporin or macrolides such as erythromycin or azithromycin can be prescribed (Dalal et al., 2017).

Cornea and conjunctiva

The cornea is the clear outer layer of the eye that allows light to enter and become focused through the lens onto the retina. The conjunctiva is the thin membrane that covers the front surface of the eye and the inner surface of the eyelids. The main purpose of this outer layer is to protect structures inside the eye, as it is the interface between the eye and the environment. This part of the eye is the body's most valuable defense against infection (Biber, 2013).

Conjunctivitis

Conjunctivitis is a common condition that causes dilation of the conjunctival blood vessels, resulting in inflammation. It presents with a red eye and is highly contagious. Diagnosis of conjunctivitis includes assessment of visual acuity (which should be minimally affected) and corneal, including with fluorescein staining to exclude corneal ulceration or infection (Watson et al., 2018). Fig. 3 is an algorithmic approach to diagnosing and treating conjunctivitis, based on signs and symptoms.

Acute bacterial conjunctivitis

Acute bacterial conjunctivitis is more common in children. The most common bacteria are *Haemophilus influenzae*, *Streptococcus pneumoniae* and *S. aureus* (Sheikh and Hurwitz, 2006). Direct transmission of pathogens onto the conjunctiva leads to infectious conjunctivitis. The onset of the infection is sudden, and patients usually complain of irritation, foreign-body sensation, redness and sticky lids in the morning. Discharge is purulent or mucopurulent and symptoms are usually unilateral but may be bilateral (Fig. 2) (Watson et al., 2018).

Fig. 2 Conjunctivitis—discharge at medial canthus.

Diagnosis can be made through clinical examination alone. However, conjunctival swabs can be obtained where copious purulent discharge, along with clinical suspicion, make the diagnosis of gonococcal or chlamydia infection more likely (Beal and Giordano, 2016; Azari and Barney, 2013) or in the event of recurrent conjunctivitis.

In general, most cases resolve within 7 days without treatment. In patients who present with purulent discharge or with a compromised ocular surface (e.g., dry eyes), it is reasonable to prescribe a topical antibiotic. Studies have found that topical antibiotics confer modest benefits in improving symptom resolution (Varu et al., 2019). Treatment may reduce transmissibility with broad-spectrum topical antibiotics recommended for 5–7 days. The initial treatment recommended by Therapeutic Guidelines is chloramphenicol 0.5% or framycetin 0.5%, 1 drop into the affected eye, four times a day for up to 7 days (Table 2) (Guidelines, 2014) (Fig. 2).

Gonococcal conjunctivitis

Conjunctivitis caused by *Neisseria gonorrhoeae* is uncommon but should be considered in sexually active young adults and neonates. The occurrence of Gonococcal conjunctivitis in neonates is most likely due to maternal transmission during birth. In older age groups, it is associated with sexually transmitted infections (STIs). If left untreated it can lead to meningitis and/or blindness (Belga et al., 2019).

Patients may experience erythema of the eyelids, discharge and conjunctival hyperemia. In non-neonatal populations, Gonococcal conjunctivitis should be considered in sexually active individuals that present with conjunctivitis with or without genital symptoms. Conjunctival swabs for gram staining and culture for *Neisseria* species should be obtained to confirm the diagnosis. Gonococcal conjunctivitis requires systemic treatment as topical antibiotic therapy alone is not adequate. Recommended antibiotics include a single dose of intramuscular Ceftriaxone and oral Azithromycin or oral doxycycline (twice a day for 7 days) (Table 2). Patients should irrigate the infected eye with saline and add therapy to cover chlamydia (Varu et al., 2019) (Fig. 3).

Chlamydia conjunctivitis

Chlamydia the most common STI worldwide is caused by the bacteria *Chlamydia trachomatis*. Chlamydia conjunctivitis typically occurs in neonates (2.1.5), and adults with exposure to STIs (WHO, 2016).

Most cases of chlamydial conjunctivitis are unilateral and in adults, there is concurrent genital infection. Patients' usually experience conjunctival hyperemia, mucopurulent discharge and lymphoid follicle formation. Diagnosis is usually based on clinical findings. However, polymerase chain reaction (PCR) conjunctival swabs can be performed to confirm *C. trachomatis*. The treatment for chlamydial conjunctivitis consists of systemic treatment with a single dose of oral azithromycin or oral doxycycline (twice a day for 7 days) (Varu et al., 2019). There is no evidence that concomitant topical therapy improves outcomes.

Fig. 3 Suggested procedure for clinical approach to suspected acute conjunctivitis.

Trachoma

Trachoma is a form of chronic conjunctivitis caused by repeat infection with *C. trachomatis*. It is the leading cause of preventable blindness, globally (Resnikoff et al., 2004). It is generally seen in communities with poor hygiene and inadequate sanitation. Transmission of the disease occurs through direct personal contact with an infected person, contaminated fomites, and flies that have come in contact with the eyes or nose of an infected person (Wright et al., 2007).

C. trachomatis is part of the chlamydia genus, which is differentiated into 18 serovars (serologically variant strains). The serovars correlate with multiple medical conditions, with serovars A, B, Ba, and C correlated with trachoma which only occurs in humans (Morre et al., 2000). Patients typically experience conjunctival cicatrization which leads to entropion and trichiasis, this can then disrupt the anatomic integrity of the corneal epithelium predisposing to ulceration (Whitcher et al., 2001). Without treatment, recurrent infection can lead to scarring of the eyelids, corneal ulceration, corneal scarring and loss of vision.

Diagnosis of trachoma is made through identification of typical clinical features including conjunctival hyperemia and/or edema, mucopurulent discharge, lymphoid follicle formation and/or subepithelial keratitis with corneal neovascularization (Ubani, 2013). The presence of limbal or conjunctival follicles suggest the infection is active; however, edema may mask the presence of follicles (Tabbara, 2014).

The World Health Organization recommends the “SAFE” strategy when managing trachoma. “S” surgery for trichiasis, “A” Antibiotics for *C. trachomatis* infection, “F” Facial cleanliness, “E” Environmental changes to improve sanitation and increase access to clean water (WHO, 2020). The recommended drug of choice is azithromycin (Table 2). Doxycycline is an alternative, but azithromycin is preferred as it is a single-dose therapy. In patients with entropion and trichiasis, surgery is necessary to prevent secondary ulceration and/or infections of the ocular surface (West, 2012).

Neonatal conjunctivitis

Ophthalmia neonatorum also known as neonatal conjunctivitis presents during the first month of postnatal life (Tabbara, 2014). Neonatal conjunctivitis is classified according to its cause as either transmitted bacteria, non-sexually transmitted bacteria, viral, and/or chemical. Less than 1% of cases are caused by *N. gonorrhoeae*, however, the incidence increases to 48% in babies born to mothers infected with *N. gonorrhea* (Laga et al., 1989). Non-sexually transmitted bacterial conjunctivitis account for 30–50% of cases, and is usually caused by *S. aureus*, *Streptococcus* species, *Pseudomonas aeruginosa* and gram-negative bacteria (Infectious Diseases and Immunization Committee of the Canadian Paediatric Society, 2002).

Patients develop erythema of the eyelids, discharge and conjunctival hyperemia. Subconjunctival lymphoid tissues are absent in neonates, and therefore, conjunctival follicles are not seen in this age group, however, edema of the palpebral and bulbar conjunctiva may be noted. Gonococcal conjunctivitis is more severe than chlamydial conjunctivitis, as gonococci have the ability to penetrate intact corneal epithelium, leading to corneal edema and ulceration, which can then lead to corneal perforation and endophthalmitis if left untreated (Table 2) (Mallika et al., 2008).

Diagnosis of neonatal conjunctivitis is based on clinical examination and bacterial cultures. Conjunctival swabs and scrapings are essential in neonatal conjunctivitis, especially if the infection is caused by *N. gonorrhoeae*, as it is a medical emergency. *C. trachomatis* and *N. gonorrhoeae* are usually transmitted at the time of delivery. Treatment for neonatal conjunctivitis is shown in Table 1.

Table 1 Treatment for neonatal conjunctivitis.

Type of infection	Onset of infection after birth	Treatment
<i>Neisseria gonorrhoeae</i>	2–5 days	Hospitalization, isolation (>24 h after therapy is initiated). Topical irrigation with normal saline to remove mucopurulent discharge. Ceftriaxone in a single dose (25–50 mg/kg IM or IV, up to a maximum of 125 mg). If there is a systemic disease, treatment is required for 7–14 days depending on the nature of the invasive infection, then topical 0.5% erythromycin ointment every 2–4 h. Note: Gonococcal conjunctivitis should also be treated for chlamydia. Mothers and sexual partners should be treated as well.
<i>Staphylococcus aureus</i> , <i>Streptococcus</i> species or other gram-positive	2–5 days	Topical 0.5% erythromycin ointment four times a day for 2 weeks
<i>Chlamydia trachomatis</i>	5–14 days	Oral erythromycin syrup, 30–50 mg/kg/day and 0.5% Erythromycin ointment four times a day for 2 weeks
<i>Pseudomonas aeruginosa</i> or other gram-negative	5–18 days	Topical 0.3% gentamicin or 0.3% tobramycin four times a day for 2 weeks

Bacterial keratitis

Bacterial keratitis is the most common cause of microbial keratitis. It is an ophthalmic emergency requiring immediate attention as it can progress rapidly. It is a significant cause of corneal blindness (Allan and Dart, 1995; Cabrera-Aguas et al., 2019; Watson et al., 2019), and one of the most common causes of visual impairment in working age adults (Whitcher et al., 2001). Predisposing risk factors include contact lenses, trauma, ocular surface disease, history of a corneal transplant and topical steroid use (Green et al., 2008). The type of causative organism varies according to the climate and geographical region and patient's risk factors (Cabrera-Aguas et al., 2019; Asbell et al., 2008).

The most common causative organisms include *S. aureus*, *Coagulase-negative staphylococci* (CoNS), *S. pneumoniae*, *P. aeruginosa* and *H. influenzae* (Cabrera-Aguas et al., 2019; Asbell et al., 2008). *P. aeruginosa* has been reported to be the most common causative organism implicated in bacterial keratitis among contact lens wearers (Willcox, 2007; Khoo et al., 2020). Patients with bacterial keratitis usually experience pain, photophobia, irritation, purulent discharge and reduced vision. They will also present with redness, discharge, corneal ulcer, corneal infiltrates and/or a hypopyon (Fig. 4).

Diagnostic laboratory investigation such as corneal scrapes should be performed to identify the causative organism and antibiotic susceptibility and resistance. Corneal ulcers should be scraped for staining and culturing. Samples can be collected at the area of corneal infiltration. Superficial corneal samples are inoculated onto 2 glass slides for microscopy and culture media (which includes 2 blood agars, chocolate agar, Sabouraud's agar slope and cooked meat medium) (Ngo et al., 2019). Other media such as brain heart infusion broth, thioglycolate broth, non-nutrient agar may be used (Leck, 2009; Preferred Practice Pattern, 2013). A corneal biopsy can also be performed in progressive cases where a negative result has been obtained from corneal scrapes or the organism identified does not match the clinical picture. A lamellar corneal biopsy can be taken using a dermal trephine or freehand dissection, the specimen is divided into two halves for histopathological and microbiological analysis (Robaei et al., 2018).

The severity of bacterial keratitis can be divided into mild, moderate and severe; this is typically done for clinical trials (Constantinou et al., 2007; Herretes et al., 2014). Mild corneal ulcers are those less than 2 mm in size with the depth of the ulcer less than 20% or 100 µm corneal thickness. Superficial infiltrates near the ulcer may also be seen. Moderate corneal ulcers range between 2 and 5 mm in size, depth of 20–50% (100–275 µm) of the cornea, with dense infiltrates extending to the mid stroma. Severe ulcers are 5 mm or larger, with a depth of more than 50% (>275 µm) and dense infiltrates reaching the deep layers of the corneal stroma (Tabbara et al., 2014). Increasing severity is generally associated with poorer outcomes (Khoo et al., 2020; Green et al., 2007).

The treatment has to be empiric as laboratory results can take over 48 h, and the infection can progress rapidly without treatment. Broad-spectrum topical antibiotics are the mainstay of treatment and should be used until culture results are available (Table 2). For mild to moderate ulcers, 1–2 drops of fluoroquinolone (e.g., ciprofloxacin 0.3% or ofloxacin 0.3%) every hour for 48 h, tapered to every 4 h until healed is recommended. For severe keratitis, fortified antibiotics (e.g., cephalothin 5% plus gentamicin 0.9%) 1–2 drops hourly for 48 h, then reduce frequency according to treatment response (Alam and Bastakoti, 2015). Treatment should be modified based on the results of culture and susceptibility testing (Preferred Practice Pattern, 2013; Guidelines, 2014) (Table 2).

Fig. 4 Bacterial keratitis. The central cornea has an epithelial defect and conjunctival inflammation.

Table 2 Bacterial infections of the cornea and conjunctiva.

Disease	Pathogen	Signs and symptoms	Transmission	Treatment
Acute bacterial conjunctivitis	<i>H. influenzae</i> , <i>S. pneumoniae</i> , <i>S. aureus</i>	Inflammation of conjunctiva with purulent crusting, discharge	Exposure to secretions from infected individual	Broad-spectrum topical antibiotics
Gonococcal conjunctivitis	<i>N. gonorrhoeae</i>	Inflammation of conjunctiva with hyperpurulent discharge, eyelid erythema	Direct sexual contact with infective secretions	Systemic Ceftriaxone, Azithromycin or Doxycycline
Trachoma	<i>C. trachomatis</i>	Chronic conjunctivitis, trichiasis, corneal scarring; may lead to blindness	Exposure to infected individual, contaminated fomites, or through flies	Systemic Azithromycin
Neonatal conjunctivitis	<i>C. trachomatis</i> , <i>N. gonorrhoeae</i>	Inflammation of conjunctiva, purulent discharge, eyelid erythema, corneal ulceration/perforation; may lead to blindness	Exposure to pathogens in the birth canal of infected mother with chlamydia or gonorrhea	Systemic Erythromycin for <i>C. trachomatis</i> Topical Erythromycin for <i>N. gonorrhoeae</i>
Bacterial keratitis	<i>CoNS</i> , <i>S. aureus</i> , <i>S. pneumoniae</i> , <i>P. aeruginosa</i> , <i>H. influenzae</i>	Blurred vision, redness and irritation to eye, photophobia, corneal ulceration, progressive corneal scarring; may lead to blindness	Exposure to pathogens (e.g., contact lens wear, trauma)	Broad-spectrum topical antibiotics (preferably fluoroquinolones)

Uveitis

Uveitis is not a single disease; it is a generic term that encompasses more than 30 different entities; some infective, some either autoimmune or auto-inflammatory and many where the cause is unclear. Some uveitides are ocular manifestations of systemic disease while others are disorders restricted to the eye. The term is used to describe inflammation of the uveal tract of the eye (iris, ciliary body, and the choroid). Uveitis can be classified as anterior, intermediate, posterior, or pan-uveitis based on the primary anatomical location of the inflammation in the eye (Table 3) (Jabs et al., 2005).

It can affect people of all ages, with the incidence varying significantly due to geographic location and age of patient (Acharya et al., 2013; Hwang et al., 2012; Gritz and Wong, 2004). Anterior uveitis is the most prevalent form of uveitis, accounting for approximately 50% of cases (Wakefield et al., 2011). Symptoms can range from conjunctival injection, photophobia and pain to complete loss of vision. Bacterial causes of uveitis include: tuberculosis (*Mycobacterium tuberculosis*), syphilis (*Treponema pallidum*), Lyme disease (*Borrelia burgdorferi*), and Whipple's disease (*Tropheryma whipplei*).

Diagnosis of uveitis is based on the patients' medical history, clinical features and laboratory testing. Symptoms and signs vary depending on the location of inflammation (Table 3). Identifying the likely cause of uveitis critically depends taking a careful thorough history, a review of systems and complete examination of both eyes. Multi-modal ocular imaging such as digital fundus photography, fundus fluorescein angiography (FFA), fundus autofluorescence (FAF), optical coherence tomography (OCT) and ultrasonography are often performed to characterize different forms of posterior and pan-uveitis. Laboratory testing can be performed to diagnose a specific underlying infectious disease based on clinical suspicion such as: QuantiFERON gold testing to determine exposure to tuberculosis, and Fluorescent treponemal antibody absorption (FTA-ABS) and rapid plasma regain (RPR) to confirm a diagnosis of syphilis (Table 3).

Treatment for infectious uveitis remains a therapeutic challenge for ophthalmologists. The mode of treatment varies greatly based on the infectious etiology. Management typically involves systemic antibiotic therapy with or without the use of corticosteroids. This will be discussed in more detail.

Table 3 Anatomical classification of uveitis and common key signs and symptoms.

Type of uveitis	Primary site of inflammation	Signs and symptoms
Anterior	Anterior chamber	Symptoms: redness, painful eye Signs: anterior chamber cell and flare, posterior synechiae, keratic precipitates
Intermediate	Vitreous cavity and pars plana	Symptoms: worsening floaters, decreased vision Signs: vitreous cell and haze, pars plana snowbank, cystoid macular edema
Posterior	Retina and choroid	Symptoms: worsening vision, visual field changes Signs: chorioretinal lesions, retinal whitening, vascular sheathing
Panuveitis	Anterior chamber, vitreous cavity, pars plana, retina and choroid	Symptoms: red, painful eye, severely decreased visual acuity, floaters Signs: anterior chamber cell and flare, vitreous cell and haze, chorioretinal lesions, retina whitening

Intraocular tuberculosis

Tuberculosis (TB) is an infection caused by *Mycobacterium tuberculosis*. The disease is thought to affect the lungs in 80% of patients, with the remaining 20% being affected in areas such as the gastrointestinal system, lymphoreticular system, central nervous system, musculoskeletal system, skin, liver and eyes (Shakarchi, 2015). Adults in their productive years and people infected with HIV are at risk of TB. However, the disease can affect all age groups. Ocular TB is an important cause of uveitis, the prevalence varies from 0.5–11% depending on the region (Henderly et al., 1987; Al-Shakarchi, 2014; Mercanti et al., 2001). A recent multinational study identified immigrants as a high-risk group to develop intraocular TB (Agrawal et al., 2018).

Intraocular TB is a complex disease as it is a great mimicker of various uveitis entities. This is partly due to the location of the infection, host response and the virulence of the organism (Gupta et al., 2007). Clinical presentations of intraocular TB are anterior uveitis, intermediate uveitis, posterior uveitis and pan-uveitis, retinitis, retinal vasculitis, neuroretinitis, optic neuritis, endogenous endophthalmitis, panophthalmitis, and scleritis.

Anterior uveitis can present as unilateral or bilateral chronic granulomatous disease that manifests as granulomatous keratic precipitates and is sometimes associated with iris nodules or granulomas (Tabbara, 2005; Gupta et al., 2007). The presence of anterior chamber inflammation associated with small grayish-yellow or reddish nodules in the iris or small translucent nodules at the pupillary margin (Albert and Raven, 2016). During relapse, mutton fat keratic precipitates may develop, along with extensive posterior synechiae, cataract and vitritis (Gupta et al., 2007).

In intermediate uveitis, patients present with a low-grade, chronic vitritis, vitreous snowballs and snow banks and peripheral vascular sheathing (Ahmed and Biswas, 2016).

In posterior and pan-uveitis, the ocular changes can be divided into choroidal tubercles, choroidal tuberculoma, subretinal abscess and serpiginous-like choroiditis.

- Choroidal tubercle is the most common manifestation of TB posterior uveitis. It has been suggested that this occurs as a result of hematogenous spread. They appear as small grayish white to yellow nodules and may be unilateral or bilateral (Ahmed and Biswas, 2016). Occasionally, a tubercle may continue to grow into a solitary mass called tuberculoma (Gupta et al., 2007).
- Choroidal tuberculoma is less common. They can be located anywhere in the choroid (e.g., macula, posterior pole, equator, or in juxtapupillary location). These large solitary mass may mimic a tumor. Hemorrhages and retinal folds may be seen on the tuberculoma surface and in later stages, the overlying retina may detach (Ahmed and Biswas, 2016).
- Subretinal abscess may be present in patients with disseminated TB with little overlying vitreous inflammation. Multiplication of the bacilli in the caseous material of the granulomas can lead to liquefaction necrosis and abscess formation. They are usually yellow in color indicating liquefaction necrosis (Gupta et al., 2007).
- Serpiginous choroiditis is a rare, chronic, recurrent inflammation that primarily involves the choroid and choriocapillaris. The lesions typically appear as gray-white to yellow with ill-defined edges, beginning in a peripapillary location and spreading centrifugally with multiple recurrences. Atypical patterns of serpiginous choroidopathy are now recognized as caused by TB. Such patients may have unilateral involvement or not involve the optic disc and peri-papillary retina. The choroiditis regresses following anti-tubercular drug therapy (Ahmed and Biswas, 2016).

Tuberculosis isolated in the retina is rare and involvement may be mostly secondary to choroiditis. Tubercular retinal vasculitis typically presents as peripheral occlusive retinal vasculitis with inflamed retinal vessels and features of distal retinal ischemia (Fig. 5) (Gunasekeran et al., 2019). Tubercular retinal vasculitis presenting features are often similar to Eales disease. Eales disease is a

Fig. 5 Tuberculosis occlusive retinal vasculitis. Optos fundus image showing widespread severe occlusive retinal vasculitis.

poorly understood form of retinal vasculitis, that is typically described as an idiopathic obliterative vasculopathy involving peripheral retina of young adults (Bodaghi and Lehoang, 2000). Recently, this has been relabeled as either tubercular retinal vasculitis or idiopathic retinal vasculitis, depending on whether it is accompanied by evidence of TB (Agrawal et al., 2017a; Gunasekaran et al., 2019; Biswas et al., 2013).

Optic neuropathy develops either from direct infection induced by *M. tuberculosis* or from a hypersensitivity to the infectious agent. The involvement of the nerve may manifest as an optic nerve tubercle, papillitis, papilledema, optic neuritis, retrobulbar neuritis, or neuro-retinitis (Gupta et al., 2007; Ray and Gragoudas, 2001). Neuro-retinitis may develop from the spread of the mycobacteria to the juxtapupillary retina from the choroiditis (Ray and Gragoudas, 2001).

Endogenous endophthalmitis has an acute onset and progresses rapidly with the destruction of the intraocular tissue (Fig. 6). Severe inflammation causes hypopyon, purulent material in the anterior chamber and involvement of the cornea (Gupta et al., 2007). These clinical presentations sometimes hinder the diagnosis of intraocular TB. In the posterior segment, intense inflammation of the choroid causes the formation of large subretinal abscesses. If left untreated, it can eventually burst into the vitreous cavity presenting itself as endophthalmitis or panophthalmitis. Furthermore, in panophthalmitis, the sclera may sometimes be involved resulting in globe perforation (Raina et al., 2000).

The difficulty in managing TB uveitis is contributed by its ability to affect any tissue in the eye (Agrawal et al., 2017a; Gupta et al., 2007; Sharma et al., 2017). Furthermore, the lack of uniformity in diagnostic criteria makes the diagnosis and management of TB uveitis difficult. The Collaborative Ocular Tuberculosis Study (COTS)-1 group developed the following diagnostic criteria to aid the diagnosis of TB uveitis. A diagnosis of TB is established if a patient satisfied both criteria 1 and 2 and at least one of criteria 3 and 4 (Agrawal et al., 2017b).

1. Clinical signs suggestive of TB uveitis, including the following:
 - i) Anterior uveitis (granulomatous or non-granulomatous), iris nodules and ciliary body granuloma.
 - ii) Intermediate uveitis (granulomatous or non-granulomatous with exudates in the pars plana, with or without inflammatory cells in the vitreous).
 - iii) Posterior and pan-uveitis, choroidal tubercle, choroidal granuloma, subretinal abscess, and serpiginous-like choroiditis.
 - iv) Retinitis, retinal vasculitis, neuroretinitis, optic neuritis, endogenous endophthalmitis, panophthalmitis, and scleritis.
2. Exclusion of other uveitic entities, where relevant, based on clinical manifestations of disease and regional epidemiologic findings.
3. Corroborative investigations
 - i) Positive Mantoux test result.
 - ii) Interferon γ release assay, such as QuantiFERON TB Gold.
 - iii) Evidence of healed or active TB on chest radiography.
4. Investigations that document the mycobacteria or its genome:
 - i) Demonstration of acid-fast bacilli by microscopy or culture of *M. tuberculosis* from ocular fluid.
 - ii) Positive PCR from ocular fluid for IS 6110 or other conserved sequences in mycobacterial genome.
 - iii) Evidence of confirmed active extrapulmonary TB (by microscopic examination or culture of a tissue sample from the affected tissue).

Fig. 6 Endogenous Endophthalmitis. Ill-defined white area of focal choroiditis that has broken through into the retina.

The treatment of intraocular TB is complex, as inappropriate management can result in life-threatening consequences. Ocular TB is generally treated under the same guidelines as active pulmonary and extrapulmonary TB. Anti-tuberculosis treatment (ATT) for intraocular TB consists of a combination of isoniazid, rifampicin, ethambutol and pyrazinamide initially for 2 months. Followed by a choice of two of the ATT over the following 4–7 months (American Thoracic Society; CDC; Infectious Diseases Society of America, 2003; World Health Organization, 2010). Low-dose systemic adjunctive corticosteroid therapy may be used for 4–6 weeks with multidrug ATT to limit the damage to the ocular tissues. However, corticosteroid alone without concomitant ATT should be avoided as it can cause panophthalmitis or cause a flare-up of systemic tuberculosis by activating a latent infection.

Syphilis

Syphilis is a sexually transmitted infectious disease caused by *Treponema pallidum*. The most common ocular manifestation of syphilis is uveitis. Risk factors include: men who have sex with men, unprotected sexual intercourse and co-infection with HIV (Aldave et al., 2001). Syphilis is commonly called the great mimicker and it can present as any form of inflammatory eye disease. Excluding syphilis infection serologically is the only investigation routinely performed in all patients presenting with uveitis. Syphilis can cause any form of uveitis: granulomatous or non-granulomatous anterior uveitis, intermediate uveitis, posterior or pan-uveitis (Fig. 7) (Barile and Flynn, 1997).

Diagnosis of the infection is based on serologic testing. Most laboratories have switched to a reverse screening algorithm and perform Treponemal specific tests to screen for exposure to syphilis as these antibodies are positive for life following infection. These include enzyme immunoassay, FTA-ABS, *T. pallidum* particle agglutination, *T. pallidum* hemagglutination, and chemiluminescence immunoassay. Non-treponemal tests are used to determine active untreated infection. Their titer will fall following treatment (Davis, 2014; Kiss et al., 2005).

Management for syphilitic uveitis consist of 10–14 days of intravenous antibiotics of penicillin G at 3–4 million units every 4 h (Lin, 2015). Adjunctive therapy with topical and oral steroids can be used to decrease the inflammatory response generated by active infection and to prevent a Jarisch-Herxheimer reaction associated with treating the infection (Kiss et al., 2005; Barile and Flynn, 1997).

Lyme disease

Lyme disease is a tick-borne infection caused by *Borrelia burgdorferi* and is a common tick-borne infection worldwide, that is endemic in Europe and North America (Piesman and Gern, 2004). The disease is commonly reported in Caucasians but can infect all races (Fix et al., 2000).

The clinical manifestation of the disease has been divided into three stages: early, disseminated, and late. The early localized disease is distinguished by erythema migrans at the site of the tick bite that occurs 7–10 days after the bite, with fever and lymphadenopathy. The disseminated stage develops 3–12 weeks after the initial infection and may manifest with erythema chronica migrans, lymphocytoma, neurologic (e.g., dizziness, headache) and cardiac manifestations (e.g., chest pain, palpitations and dyspnea). Late-stage Lyme disease may occur months or years after the initial infection. Typical features include neurological and rheumatological involvements and skin disorders.

Ocular inflammation typically occurs in the disseminated and late stages of the disease; however, it is uncommon. During the disseminated stage it may manifest as anterior, intermediate, posterior or pan-uveitis. Like syphilis it can mimic many forms of uveitis. In the late stage, keratitis is the most common ocular manifestation, episcleritis is less common (Amer et al., 2009; Mikkila et al., 2000).

Fig. 7 Syphilitic retinitis. Severe vitreous inflammation resulting in hazy view of the retina. Swollen inflamed optic disc and large area of peripheral retinitis.

The diagnosis of Lyme disease is based on clinical assessment and importantly travel to or residence in an endemic region. There may or may not be a history of tick bite. Serological testing such as ELISA for IgM and IgG, followed by a confirmatory Western blot test are needed to confirm the diagnosis. The specificity and sensitivity of testing varies widely and care should be taken as a false-positive serological test may lead to incorrect diagnosis (Johnson et al., 1996).

The treatment for Lyme disease is based on a combination of antibiotics and corticosteroids. The recommended antibiotics include doxycycline, amoxicillin, cefuroxime or ceftriaxone (Wormser, 2006). Topical and systemic corticosteroids are used to treat the associated inflammation (Winward et al., 1989).

Posterior segment

The posterior segment of the eye is made up of the vitreous humor, retina, choroid and optic nerve. Bacterial infection of the posterior segment, with manifestations such as optic neuropathy, retinitis and choroiditis most commonly occur in conjunction with uveitis for example with tuberculosis and syphilis, however, cat-scratch disease, Lyme disease and Whipple's disease.

Cat scratch disease

Cat scratch disease (CSD) is a worldwide, self-limited, systemic illness caused by the gram-negative bacillus, *Bartonella henselae* (Ksiaz et al., 2019). Cats are the main carriers of the infection, and the cat flea is an important vector for the transmission of the organism among cats (Pennisi et al., 2013). The disease is transmitted to humans by scratches, licks, and bites of domestic cats (Ksiaz et al., 2019). It typically causes a mild illness in immunocompetent humans.

The clinical systemic manifestation of CSD includes fever, malaise, anorexia, and lymphadenopathy at the site of inoculation. The onset of symptoms occurs approximately 2–3 weeks after inoculation. Typical ocular features are adnexal and anterior segment involvement, particular Parinaud oculo-glandular syndrome, which is common in CSD. The infection may also cause unilateral or bilateral neuro-retinitis and optic papillitis classically associated with a macular star. There is often mild anterior chamber and vitreous inflammation (Mabra et al., 2018). The onset of visual symptoms occur approximately 4 weeks following inoculation and is usually unilateral. Patient experience decreased in visual acuity ranging from 6/6 to light perception (Solley et al., 1999). Neuro-retinitis usually has a self-limited course, and most patients recover within several weeks to months (Ksiaz et al., 2019; Anderson and Neuman, 1997). The macular star resolves within 8–12 weeks but can be present for up to 1 year.

Diagnosis of CSD is made through patient history, clinical features and laboratory results. The typical history of prodromal symptoms, lymphadenopathy, and cat exposure strengthens the diagnosis, specifically when presenting in younger adults or children. There are various laboratory and histological techniques can be used to diagnose CSD. A lymph node or conjunctival biopsy can be performed, and the tissue stained with Warthin-Starry staining. However, the most common diagnostic technique is serological testing, either with ELISA or indirect fluorescence assay (IFA). The sensitivities and specificities differ with both techniques. The preferred test is the IFA test as it has a higher specificity of 95% (Ksiaz et al., 2019). PCR can also be performed on tissue or blood. PCR can differentiate between different *Bartonella* species (Relman et al., 1990).

For immunocompetent patients, the disease has a self-limited course, and for patients with mild to moderate case, treatment may not be necessary. However, treatment is given to patients with severe ocular or systemic complications. Antibiotics such as azithromycin, doxycycline, ciprofloxacin, trimethoprim-sulfamethoxazole, or rifampicin may be used (Prutsky et al., 2013). Preventative measures such as washing and disinfecting any wounds immediately after a cat scratch or bite, and avoiding stray cats is recommended to prevent CSD (Nelson et al., 2016; Gupta et al., 2004).

Whipple's disease

Whipple's disease is a rare but chronic, multisystem disease caused by the gram-positive bacillus, *Tropheryma whippiei*. It occurs more frequently in middle-aged white men, with a male to female ratio of 4:1 and the mean onset of symptoms at 55 years of age (Dolmans et al., 2017). Involvement of the eye is rare in patients with Whipple's disease but may occur in isolation or with gastrointestinal, neurologic or other systemic manifestations. A number of ocular manifestations in Whipple's disease have been reported such as uveitis, retinitis, choroiditis, retinal vasculitis, retinal hemorrhages and cystoid macular edema (Jelliti et al., 2014; Chan et al., 2001).

Ocular diagnosis of Whipple's disease remains a challenge, especially in the absence of gastrointestinal symptoms. Diagnosis is usually via biopsy of the duodenal mucosa but can also be confirmed via PCR analysis of cerebrospinal or vitreous fluids and/or peripheral blood (Relman et al., 1992). Positive results are determined either through positive PCR detection of *T. whippiei*, PAS staining showing foamy macrophages in biopsy specimen or immunohistochemical staining with *T. whippiei* antibodies (Chan et al., 2001; Jelliti et al., 2014).

Treatment of ocular Whipple's disease consists of oral antibiotics (trimethoprim-sulfamethoxazole (TMP-SMX) and rifampin) for at least 1 year to prevent relapse (Keinath et al., 1985). Third-generation cephalosporins are effective for *T. whippiei* resistant to TMP-SMX (Touitou et al., 2012).

Endophthalmitis

Infectious endophthalmitis is an inflammatory condition of the intraocular cavity (i.e., the aqueous or vitreous humor) caused by microorganisms (Callegan et al., 2002). The most common causative organisms are CoNS, *S. aureus*, *Streptococci* species, and *Bacillus* species (Durand, 2013; Okada et al., 1994). It is an ocular emergency requiring immediate attention to prevent permanent loss of vision. Endophthalmitis is uncommon and its incidence is dependent on the cause.

There are two types of endophthalmitis; exogenous and endogenous. Exogenous endophthalmitis is the most common cause of endophthalmitis and arises from infecting organisms gaining entry into the eye by direct inoculation, such as from cataract surgery, intravitreal injections (for conditions such as age-related macular degeneration and diabetic retinopathy), penetrating ocular trauma, corneal infection or via a filtering bleb (for glaucoma) (Durand, 2017). Endogenous endophthalmitis occurs when infectious organisms are hematogenously disseminated to the eye from a distant source of infection, such as the brain, heart, liver, lungs and urinary tract (Callegan et al., 2002; Scott et al., 1996). Risk factors include: recent dental surgery, intravenous cannula and IV lines, sepsis, surgery, immunocompromised, malignancy and IV drug use (Relhan et al., 2018).

Endophthalmitis usually presents 3–5 days after the procedure or injury with acute onset of pain, floaters, photophobia, blurred vision and light perception visual acuity. Endophthalmitis from lower virulence organisms may not present for weeks after infection. Clinical features usually include: redness, hazy media, anterior chamber cells and hypopyon (Fig. 8) (Durand, 2017; Taban et al., 2005). The most common causative organisms are CoNS, *S. aureus*, streptococci species (Ng et al., 2005; Durand, 2017). Bacteria such as CoNS typically colonize the conjunctiva and can be introduced to the inner ocular cavity during injury, surgery or trauma.

The diagnosis is based on patient history, clinical features and laboratory results. The onset of symptoms is a good indication of whether it has a bacteria or fungal etiology. Bacterial endophthalmitis typically presents acutely in a shorter timeframe, often within days of a penetrating event compared to fungal endophthalmitis which has a more sub-acute presentation, worsening over days to weeks (Durand, 2017). Exogenous endophthalmitis is commonly unilateral and there is a history of a recent penetrating event (Kernt and Kampik, 2010). Endogenous endophthalmitis is also most often unilateral, but in a third of cases can be bilateral (Chee and Jap, 2001; Sadiq et al., 2015).

Microbiological specimens of the vitreous should be performed to identify the causative organism, the vitreous can be obtained either by vitreous tap or pars plana vitrectomy (PPV). According to the Endophthalmitis Vitrectomy Study (EVS), the decision between a vitreous tap and vitrectomy for patients should be determined based on the presenting visual acuity (Anon, 1995). For patients with light perception vision or diabetes, a PPV should be performed as it increased the likelihood of achieving a better visual outcome. For patients with visual acuity better than light perception, there was little difference with either method (Anon, 1995). Additional tests can be performed to confirm diagnosis such as fundoscopic examination can reveal intraocular inflammation. Ultrasound evaluation can be performed to identify vitritis, or chorioretinal infiltrates (Sadiq et al., 2015).

Urgent management with intravitreal, broad spectrum antibiotics is critical to preserve vision (Guidelines, 2014). Broad-spectrum intravenous, topical and potentially intravitreal antibiotics should be administered after microbial sampling. Treatment should be modified based on the results of culture and susceptibility testing (Sadiq et al., 2015). Antibiotics recommended for empirical intravitreal therapy include vancomycin, ceftazidime, amikacin and 4th generation fluoroquinolones such as moxifloxacin (Guidelines, 2014; Barry et al., 2007). Often antibiotic treatment is combined with PPV as besides providing a diagnostic sample, it reduces the infective and inflammatory load (Anon, 1995).

Herpes simplex virus (HSV), varicella-zoster virus (VZV) and cytomegalovirus (CMV) belong to the Herpesviridae family, a large group of enveloped, double-stranded DNA viruses that commonly affect humans (Liesegang, 2001; Koganti et al., 2019; Tsatsos et al., 2016).

Herpes simplex virus has two forms: HSV-1, associated with ocular and perioral pathology and HSV-2 with anogenital infections (Farooq and Shukla, 2012; Guess et al., 2007; Tsatsos et al., 2016). Ocular HSV infections represent a significant burden of disease worldwide (White and Chodosh, 2014). An estimated 500,000 people have ocular HSV in the United States alone, and treatment of new and recurrent cases costs the country US\$ 17.7 million annually (Farooq and Shukla, 2012). Extrapolation of the incidence of new and recurrent cases to 2011 estimated the United States population yields an estimate of 64,499 new and recurrent cases per year in the United States (White and Chodosh, 2014).

Varicella-zoster virus along with HSV-1 and HSV-2 belong to the subfamily alphaherpesvirinae. These viruses have the widest host range and short replicative cycle compared to the subfamilies beta and gammaherpesvirinae (Gershon et al., 2015; Koganti et al., 2019). Primary infection with VZV manifests as varicella (chickenpox). After the episode of varicella, the virus travels in a retrograde manner to the dorsal root and cranial nerve sensory ganglia becoming latent. As cellular immunity declines with age or in immunocompromised patients, VZV reactivates causing herpes zoster (HZ or shingles; Gershon et al., 2015; Bowling, 2016; Li, 2018; Liesegang, 2008). Following HZ patients may be left with ongoing pain in the area affected, this condition is known as post-herpetic neuralgia (PHN). Epidemiological data has been reported from developed countries with long life expectancies. The population incidence of zoster is 3–4 per 1000 person-years of observation (Weitzman et al., 2013; Yawn et al., 2007; Li, 2018). The incidence of HZ and PHN increases significantly with age (Weitzman et al., 2013; Yawn et al., 2007). In an Israeli study, 12% and 3% of patients older than 65 years developed PHN or ophthalmic complications, respectively (Weitzman et al., 2013). Similarly, in a study in Olmsted County, MN, USA, PHN occurred in one-fifth of adult patients and in one-third of patients aged 79 or older (Yawn et al., 2007). By the age of 85, more than 50% of population presents at least one episode of HZ (Gershon et al., 2015).

The herpesvirus human cytomegalovirus (HCMV) belongs to the subfamily betaherpesvirinae (Koganti et al., 2019). Primary infection usually occurs in healthy individuals who may not exhibit symptoms and leads to lifelong latency of the virus in the individual. However, a serious burden of the disease results in latently infected individuals with a re-activation of the virus, particularly in those who are immunocompromised (Harthan et al., 2016; Dupont and Reeves, 2016).

Blepharoconjunctivitis

Herpes simplex virus

Blepharoconjunctivitis caused by HSV can be a manifestation of a primary infection or result from reactivation of the virus (Guess et al., 2007; Bowling, 2016). It presents after an incubation period of between 1 and 28 days, with self-limited skin lesions and a

follicular conjunctival inflammatory response which may lead to keratitis (Guess et al., 2007; Valerio and Lin, 2019). Prodromal facial and lid tingling lasts 24 h followed by the eruption of skin lesions over 48 h (Bowling, 2016). The lesions consist of grouped vesicular or vesiculopustular eruptions on the eyelids and periocular area (Guess et al., 2007; Valerio and Lin, 2019). The lesions are limited to a dermatome but not present in a sharply delineated unilateral pattern like in HZO. Other symptoms include discharge and lid swelling (Bowling, 2016). Misdiagnosis is frequent as this condition is rare. Differential diagnosis is follicular conjunctivitis such as chlamydia and meibomian gland dysfunction (Valerio and Lin, 2019).

In some patients, this condition will settle without treatment in over a week. Topical antiviral agents such as acyclovir and trifluridine are the first line therapy. Oral antiviral may be also used (Valerio and Lin, 2019; Bowling, 2016).

Herpes zoster ophthalmicus

Herpes zoster ophthalmicus (HZO) refers to herpes zoster affecting the dermatome supplied by the ophthalmic division of the fifth cranial (trigeminal) nerve (Bowling, 2016; Li, 2018; Liesegang, 2008). HZO presents more frequently in the sixth or seventh decade of life, accounting for 10–20% of HZ cases (Bowling, 2016; Tran et al., 2016; Liesegang, 2008; Vadoothker and Jeng, 2018).

Ocular involvement is common through different mechanisms: direct viral invasion causing conjunctivitis and epithelial keratitis; secondary inflammation and occlusive vasculitis causing episcleritis, scleritis, keratitis, uveitis, optic neuritis and cranial nerve palsies; and reactivation causing necrosis and inflammation in the affected sensory ganglia with cornea anesthesia and neurotrophic keratopathy (Bowling, 2016). The Hutchinson sign refers to the presence of skin lesions in the tip, side and root of nose. These areas are supplied by the external nasal nerve which is a branch of the nasociliary nerve. This sign correlates strongly to ocular involvement (Bowling, 2016; Li, 2018; Liesegang, 2008; Wehrhahn and Dwyer, 2012; Chan and Chee, 2019).

A prodromal phase of 3–5 days with tiredness, fever, malaise and headache precedes the onset of the rash. Symptoms in the involved dermatome include itching, tingling or burning sensation to a severe lancinating constant or intermittent pain, poor vision and photophobia (Vadoothker and Jeng, 2018; Bowling, 2016; Li, 2018). Older individuals with early severe pain and a large affected area are most at risk of presenting PHN (Bowling, 2016; Li, 2018). The typical cycle of skin lesions in HZO are described in Fig. 1 (Bowling, 2016). Some patients can develop “*zoster sine herpette*” which manifest without any skin rash (Li, 2018; Vadoothker and Jeng, 2018; Liesegang, 2008). Ocular symptoms tend to appear 1–4 weeks post rash onset (mean 1.82 weeks) (Vadoothker and Jeng, 2018).

In immunosuppressed patients, large hemorrhagic lesions are more common (Bowling, 2016). Long-term manifestations can present in one third of patients with HZO, increasing to 70% in patients over the age of 80 years despite the current availability of antivirals (Liesegang, 2008).

Complications associated with HZO not only affect the skin and the anterior segment but may also involve the retina, optic nerve and central nervous system (Liesegang, 2008). Periorbital edema and ptosis may occur and as the inflammation from the vesicles subsides, residual ptosis, lid scarring, deep scalp pitting, entropion, ectropion, loss of normal pigmentation and lid necrosis may follow. Conjunctivitis may also present with hyperemia, petechial hemorrhages, a papillary reaction and infrequently pseudomembranes (Liesegang, 2008). The development of any complication does not relate with the severity of the rash (Liesegang, 2008).

If the clinical diagnosis is unclear, mostly in immunodeficiency, vesicular fluid can be tested using PCR, immunomicroscopy or culture. PCR may be positive in 40% of cases as the viremia lasts for some days (Bowling, 2016).

Fig. 1 Typical cycle of skin lesions in herpes zoster ophthalmicus.

Oral antiviral must be preferably commenced within 72 h of the rash onset. The antivirals reduce the severity, duration of the episode and the risk of PHN. Antiviral therapies include the following (Bowling, 2016; Li, 2018; Wehrhahn and Dwyer, 2012; Jain et al., 2019; Dworkin et al., 2007; Therapeutic-Guidelines-Ltd, 2019):

- Aciclovir 800 mg, five times daily for 7 days.
- Valaciclovir 1 g, three times daily for 7 days.
- Famciclovir 500 mg, three times daily for 7 days.

Intravenous acyclovir 10 mg/kg, three times daily is only indicated in severe disease, especially for encephalitis, and for moderate to severe immunocompromised patients.

Systemic steroids are controversial but are usually prescribed for moderate to severe disease with neurological complications. A typical regimen is prednisolone 60 mg daily for 4 days, followed by 40 mg for 4 days, then 20 mg for 4 days.

Conjunctivitis

Adenovirus, a non-enveloped double-stranded DNA virus, is the causal organism of 90% of viral conjunctivitis cases (Bowling, 2016; Watson et al., 2018; Azari and Barney, 2013). It presents more commonly in adults and is self-limiting (Watson et al., 2018; Bowling, 2016). Incubation and communicability periods are approximately 5–12 days and 10–14 days, respectively (Azari and Barney, 2013).

This is a highly contagious infection with a risk of transmission between 10% and 50%. The virus can survive on dry surfaces for weeks and the viral shedding may occur for many days before the symptom's onset. Transmission occurs by direct contact with respiratory or ocular secretions via contaminated fingers, medical instruments, swimming pool water or personal items (Azari and Barney, 2013; Bowling, 2016).

Clinical presentation includes:

- Non-specific acute follicular conjunctivitis which is the most common clinical form of adenoviral conjunctivitis. Symptoms include unilateral watering, redness, itching and mild photophobia. The contralateral eye is commonly affected 1–2 days later but typically less severely. Moreover, respiratory symptoms such as sore throat or rhinorrhoea can occur. Signs include eye lid edema, pre-auricular lymphadenopathy in up to 50% of cases, prominent conjunctival hyperemia and follicles and papillae in the superior tarsal conjunctiva (Bowling, 2016; Azari and Barney, 2013) (Fig. 2).
- Pharyngoconjunctival fever is caused by adenovirus serovars 3,4 and 7. It spreads within families with upper respiratory tract infections. Keratitis may be seen in a third of the cases and rarely severe. Clinical features include sore throat which is characteristically severe with a sudden onset of high fever, bilateral conjunctivitis and periauricular lymphadenopathy (Bowling, 2016; Azari and Barney, 2013).
- Epidemic keratoconjunctivitis is caused by adenovirus serovars 8, 19 and 37 and is the severe form of adenoviral infection. Clinical features include watery discharge, hyperemia, chemosis and ipsilateral lymphadenopathy (Azari and Barney, 2013). Most cases (80%) present with a severe keratitis and photophobia (Bowling, 2016).

Diagnostic tests are usually not needed; however, they should be considered for non-resolving cases or for unclear diagnosis. PCR is sensitive and specific for viral DNA. Viral culture is the gold standard but is costly and slow. Sensitivity is variable but specificity is 100%. A “point-of-care” immunochromatography test takes 10 min to detect adenoviral antigen in tears with an excellent sensitivity and specificity (Bowling, 2016).

Fig. 2 This photograph illustrates follicles in adenoviral conjunctivitis.

Adenoviral conjunctivitis resolves within 2–3 weeks spontaneously. There are no specific medications for this condition. To decrease transmission risk is important to maintain a strict hand hygiene, rigorous instrument disinfection, and avoid eye rubbing and towel sharing (Azari and Barney, 2013). For symptomatic relief, lubricants four times daily and cold (or warm) compresses can be beneficial. Preservative-free preparations bring an advantage as they come in single-dose units reducing transmission risk. Topical antihistamines and vasoconstrictors may improve symptoms, especially itching. Other measures include discontinuation of contact lens wear until resolution of symptoms (Azari and Barney, 2013; Bowling, 2016; Watson et al., 2018).

Topical steroids such as prednisolone 0.5% four times daily may be needed for severe membranous or pseudomembranous adenoviral conjunctivitis. They only control the inflammation but do not shorten healing time. Topical steroids should be used with caution as they may enhance viral replication, extend the period that the patient is infectious and increase intraocular pressure if the treatment is prolonged. Removal of symptomatic pseudomembranes or membranes may be needed (Bowling, 2016).

Available antiviral medications are not beneficial and topical antibiotics do not prevent secondary bacterial infections. Their use may complicate the course of this infection by causing toxicity or allergy and/or delaying the diagnosis of other possible causes. Moreover, the indiscriminate use of topical antibiotics may increase the antimicrobial resistance of the most common causal organisms. If the condition does not improve between 7 and 10 days or the conjunctivitis is severe, patients should be referred to an ophthalmologist (Azari and Barney, 2013; Watson et al., 2018).

Keratitis

Herpes simplex virus

Herpes simplex virus keratitis (HSK) is an important cause of unilateral blindness in the developed countries due to stromal opacification (Cabrera-Aguas et al., 2018; Guess et al., 2007; Watson et al., 2018). About 500,000 people are infected with ocular herpes simplex virus in the United States alone (Azher et al., 2017; Farooq and Shukla, 2012). One fifth of people with ocular HSV infection develop stromal HSK with the attendant risk of blindness (Guess et al., 2007). Worldwide the incidence of HSK in 2012 was estimated conservatively at about 1.5 million, with 40,000 new cases of severe monocular visual impairment or blindness each year (Farooq and Shukla, 2012).

The appropriate therapy for each type of HSK depends on the correct diagnosis made by clinical observation on slit-lamp examination. A simple classification system was introduced in the “Herpes Simplex Virus Keratitis: a treatment guideline” by the American Academy of Ophthalmology (AAO) in 2014. This classification includes epithelial HSK, stromal HSK, and endothelial HSK and depends on which layer of the cornea is involved (White and Chodosh, 2014). It may also be considered as either primary or recurrent depending on whether it is the patient’s first episode (Guess et al., 2007). A history of labial cold sores or prior HSK can be the first clue to the diagnosis (Watson et al., 2018).

The severity and frequency of recurrent HSK episodes is determined by the susceptibility of the host to the virus and the local susceptibility of the host target tissue. The general susceptibility of the host to the HSV depends on their immune status. Any inherited or acquired condition that suppresses the immune system and age increase the risk of frequent ocular HSV recurrences or severe disease, mostly HSK (White and Chodosh, 2014). For example in organ transplant recipients, the immune system is compromised due to corticosteroids and immune suppressive medications (White and Chodosh, 2014). In terms of age, diagnosing and treating children with ocular HSV disease is challenging. Children tend to present with severe ocular HSV inflammatory disease, more recurrences, and complications compared to adults (White and Chodosh, 2014; Schwartz and Holland, 2000). The inflammatory response of the stromal HSK is more aggressive leading to stromal scarring, corneal opacification, and irregular astigmatism. If the vision is reduced by these changes children, typically before the age of 8 years, are likely to develop amblyopia (White and Chodosh, 2014). Bilateral ocular HSV disease occurs more frequently in children with rates of 3.4–26% and a recurrence rate within the first year of 45–50%, when compared to adults (1.3–12% and 18%, respectively). Bilateral presentation usually occurs as a manifestation of primary infection and causes more complications (White and Chodosh, 2014).

Cornea susceptibility may increase under certain conditions, including with the administration of medications, trauma, and local inflammation (White and Chodosh, 2014). Medications such as prostaglandin agonists (such as latanoprost) used to manage elevated intraocular pressure and corticosteroids may increase the risk of recurrent ocular HSV disease (White and Chodosh, 2014). Any type of ocular surgery on an eye with previous ocular HSV disease increases the risk of recurrence of the disease (Valerio and Lin, 2019). The trauma of the surgery with the local immunosuppression of the perioperative corticosteroids may be contributors. Antiviral prophylaxis is therefore recommended in the immediate perioperative period especially while the patient is on corticosteroids (White and Chodosh, 2014).

A diagnosis of HSK is mainly made clinically after assessing the patient’s history, symptoms and signs. Investigations are performed for atypical or complicated cases or when the diagnosis is uncertain and in all cases of suspected neonatal HSV infection. Viral culture and antigen or DNA detection can be useful in primary epithelial infection but not in stromal HSK as most adults are latently infected with HSV (antibody-positive) (White and Chodosh, 2014; Guess et al., 2007). Polymerase chain reaction test can detect viral DNA and quantify the number of viral copies differentiating viral shedding from replication. Variable reports of the sensitivity of PCR testing exist in different studies 70% (El-Aal et al., 2006), 98% (Kowalski et al., 2006; Kowalski) and 100% (Subhan et al., 2004). PCR is more likely to diagnose patients with typical lesions or patients who have not used antiviral

medications than the Direct Fluorescent Antibody (DFA) test. Advantages of PCR include its high sensitivity and fast results. Disadvantages include the need for a skilled technician, special equipment and appropriate parameters for ocular specimens in a clinical setting. In addition, the interpretation of this test is limited by the inability to differentiate HSV disease level from asymptomatic HSV shedding in the tear film (White and Chodosh, 2014).

The clinical features of HSK, shown in Table 1, can be identified on slit lamp examination (White and Chodosh, 2014; Azher et al., 2017; Rowe et al., 2013; Guess et al., 2007; Cabrera-Aguas et al., 2018) (Figs. 3 and 4). Commonly, the treatment for epithelial HSK is acyclovir ointment five times daily for 14 days (Watson et al., 2018). However, in some cases oral antivirals may be needed (White and Chodosh, 2014). Management of stromal HSK, endothelial HSK and keratouveitis involves referral to an ophthalmologist for oral antivirals (Acyclovir or Valacyclovir), topical steroids and close follow up (Watson et al., 2018; Fung et al., 2020).

The AAO released a treatment guideline in 2014 for epithelial HSK, stromal HSK with/without ulceration, endothelial HSK and prophylaxis (White and Chodosh, 2014). This guideline recommended for epithelial HSK, ganciclovir as the first line topical therapy and includes alternatives such as oral acyclovir, famciclovir and trifluridine. Nevertheless, ganciclovir and trifluridine are not easily accessible in Australia as there are in the United States. A study from Sydney, Australia, reported a diverse prescribing patterns for the treatment and prevention of HSK which were not in alignment with the recommendations from clinical trials (Cabrera-Aguas et al., 2018). Therefore, an evidence-based treatment guideline was developed, implemented and evaluated to standardize the initial treatment for HSK (Table 1) (Cabrera-Aguas et al., 2020; White and Chodosh, 2014; Valerio and Lin, 2019). This guideline was endorsed by the Royal Australian and New Zealand College of Ophthalmologists (RANZCO) in April 2020.

Recurrent episodes of HSK can lead to damage to the cornea nerves causing neurotrophic keratopathy. Patients present with decreased corneal sensation, blink reflex and tear production due to the damage to the sensory fibers innervating the cornea. Corneal sensation is reduced during HSV infection through unclear mechanisms but probably involving the immune system and events within the sensory ganglion. The effects of reduce corneal sensitivity ranges in severity from a irregular epithelial surface to an

Table 1 Herpes simplex keratitis treatment guideline (Cabrera-Aguas et al., 2020; Watson et al., 2018).

Indication	Signs	Antiviral therapy	Topical corticosteroid therapy
Epithelial HSK	Dendritic ulcer Geographic ulcer	Topical acyclovir 3% five times daily for 1–2 weeks. Valacyclovir 500 mg twice daily for 7 days ^a	
SHSK-U	Stromal haze/opacity without ulceration Lipid keratopathy Stromal edema Scarring Sectoral or diffuse neovascularization Corneal thinning Immune ring	Valacyclovir 500 mg once daily during topical steroid use	Prednefrin Forte 4–6 times daily tapered over >10 weeks
SHSK+U	Stromal haze/opacity with ulceration Lipid keratopathy Stromal edema Scarring Sectoral or diffuse neovascularization Corneal thinning Immune ring	Valacyclovir 1 g three times daily for 7–10 days ^b	Prednefrin Forte twice daily tapered slowly as disease comes under control
Endothelial HSK	Central focal circular area stromal edema Keratic precipitates	Valacyclovir 500 mg once to 1 g three times daily for 7–10 days ^b (There is a lack of clinical evidence to guide dosage in this situation)	Prednefrin Forte 4–6 times daily tapered over >10 weeks
Keratouveitis ^c	Stromal edema Keratic precipitates Stromal keratitis Anterior chamber cells	Valacyclovir 1 g three times daily for 7–10 days ^b	Prednefrin Forte 4–6 times daily tapered over >10 weeks
Prophylaxis ^d		Acyclovir 400 mg twice daily Valacyclovir 500 mg once daily	

Key: HSK, herpes simplex keratitis; SHSK-U, stromal herpes simplex keratitis without ulceration; SHSK+U, stromal herpes simplex keratitis with ulceration.

^aIndications: immunocompromised patients; non-compliance, inability to use or tolerate, or ocular toxicity from topical acyclovir.

^bReduce valacyclovir to prophylactic dose after 7–10 days and maintain for as long as frequent topical steroids are in use.

^cRefer patient to cornea/uveitis clinic, respectively depending on degree of corneal or uveal involvement.

^dIndications: multiple recurrences of any type of HSK, especially stromal HSK; and patients with history of ocular HSV following any ocular surgery including penetrating keratoplasty or during immunosuppressive treatment.

Fig. 3 This photograph illustrates an epithelial dendrite from herpes simplex keratitis seen with fluorescein staining and a cobalt blue light.

Fig. 4 This photograph illustrates a stromal herpes simplex keratitis with ulceration (arrow).

oval-shaped neurotrophic ulcer with a heaped-up border (Valerio and Lin, 2019; Tsatsos et al., 2016). After the infection is resolved, the cornea reinnervates with a different organization of its fibers, peptidergic content or function. If the breakdown of the epithelium is not appropriately treated as soon it is diagnosed, it may lead to corneal scarring, thinning, vascularization, perforation, or secondary corneal infection resulting in vision impairment or blindness (Tsatsos et al., 2016).

Treatments to promote epithelial growth include ocular lubricants, tarsorrhaphy, botulinum toxin-induced ptosis, growth factors and autologous plasma for early to moderate cases; and collagenase inhibitors, tissue adhesives, conjunctival flap, amniotic membrane use and penetrating or lamellar keratoplasty for more severe and complicated cases (Tsatsos et al., 2016; Valerio and Lin, 2019).

Varicella zoster virus

Herpes zoster keratitis (HZK) generally presents within 1 month of the onset of HZO involving any layer of the cornea. Epithelial and stromal HZK have been identified as risk factors for vision loss after acute phase due to the development of long-term scarring or haze. In a study from Minnesota, 6% of patients developed long-term vision loss (Li, 2018).

Epithelial HZK presents in up to 50% of patients with HZO with ocular involvement. Punctuate epithelial lesions appear 2 days after the vesicular eruption being a transient finding or coalescing into pseudodendrites around day 6 (Liesegang, 2008; Li, 2018; Aggarwal et al., 2014). Pseudodendrites are small and fine lesions, with a similar branching pattern as HSV dendrites. They are formed by swollen and heaped up epithelial cells located in the periphery of the cornea. Pseudodendrites differ from HSV dendrites as they lack the terminal bulb appearance and the central ulceration of HSV dendrites. Pseudodendrites may resolve spontaneously or progress to stromal HZK in half of the cases (Li, 2018).

Stromal HZK presents in 6–16% of patients with ocular involvement of HZO. It usually develops at day 10 of the onset of HZO after the manifestation of the epithelial lesions. Complications includes long-term nummular corneal scarring, lipid keratopathy

and dellen (Li, 2018; Liesegang, 2008). Keratouveitis/endotheliitis occurs in 1–7% of patients within a week of onset of HZO. Clinical features include localized corneal edema, cell and flare and a complement-mediated immune Wessely ring (Liesegang, 2008; Li, 2018). The degree of anterior chamber involvement varies being severe with associated hypopyon or hyphema from the vasculitis. Elevated intraocular pressure may be also present. This type of keratitis may lead to long term endothelial cell loss and corneal decompensation.

A disciform stromal keratitis may represent an HZV active infection or a zoster immune reaction. It resolves within months and may become chronic with edema and lipid keratopathy. Corneal mucous plaques or delayed pseudodendrites occur months or year later typically in a quiescent eye. Pseudodendrites vary in size, migrate and move around the cornea (Liesegang, 2008). Interstitial keratitis results from long-term HZV inflammation with corneal vascularization and lipid keratopathy, scarring and possible perforation. Nerve damage leads to neurotrophic keratopathy diminishing corneal sensation with the loss of corneal epithelial integrity and tear dysfunction (Liesegang, 2008).

Neurotrophic keratopathy may suddenly present months after HZO with diffuse epitheliopathy and chronic surface dysfunction. Subsequent calcareous plaque formation may develop. Corneal edema can be temporary but usually represents the chronic end stage of corneal endothelial destruction by the virus or the related inflammation (Liesegang, 2008).

Episcleritis or scleritis may appear in an early stage of the infection and become persistent or appear later. The scleritis may involve the limbus presenting as limbal vasculitis and sclerokeratitis resulting in a patchy scleral atrophy (Liesegang, 2008).

Oral antiviral agents must be commenced within 72 h of onset of HZO. Acyclovir, valacyclovir and famciclovir are comparable in efficacy and in the prevention of ocular complications (Li, 2018; Colin et al., 2000; Beutner et al., 1995; Tyring et al., 2000; Jain et al., 2019). Despite treatment recommendations for patients presenting with HZO, there is little consensus on the management of acute complications such as keratitis (Aggarwal et al., 2014). Diverse antiviral agents alone or in combination with topical steroids have been found to be effective in some studies for pseudodendritic keratitis despite current or recent oral antiviral therapy (Hu et al., 2010; Mortemousque, 2006; Magone et al., 2005). For example, topical ganciclovir 0.15% gel was reported to be useful in these cases (Aggarwal et al., 2014; Li, 2018). The use of corticosteroids has been controversial. Corticosteroids control the inflammation in stromal, keratouveitis/endotheliitis cases, however tapering off the drops may be challenging. In some cases, patients may need long-term topical steroids, however they need to be warned about side effects such as glaucoma and cataracts (Li, 2018).

Complications from HZO are associated with chronic and/or recurrent active HZV infections. There is evidence that suppressive oral antiviral therapy is effective in HSV disease, and as HSV share similarities with HZV; it may be reasonable to consider the use of suppressive oral antiviral therapy for HZV infections. Despite the lack of evidence, clinicians prescribe suppressive antiviral therapies in different dosages and frequencies (Lo et al., 2019). Consequently, the Zoster Eye Disease Study (ZEDS) is currently investigating whether suppressive antiviral therapy (valacyclovir 1 g daily for 1 year) reduces chronic and recurrent HZV disease in the United States with over 200 investigators at 60 participating centers (Lo et al., 2019; Jain et al., 2019; Clinicaltrials.gov, 2020).

Uveitis

Uveitis refers to the inflammation of the middle, pigmented, vascular structure of the eye. It may affect one or multiple structures in the uveal tract. Anatomically, uveitis is divided in anterior, intermediate, posterior uveitis and pan-uveitis. Anterior uveitis affects the anterior chamber, intermediate uveitis, the vitreous, posterior uveitis, the retina or choroid; and pan-uveitis, the anterior chamber, vitreous, and retina or choroid (Jabs et al., 2005).

Anterior uveitis

Anterior uveitis (AU) is the most common form of uveitis worldwide (Tsirouki et al., 2018). Anterior uveitis can be acute (sudden onset with a duration of less than 3 months), recurrent (episodes separated by a quiet period lasting over 3 months), or chronic (episodes lasting over 3 months). Acute AU typically presents with unilateral eye pain, redness, blurred vision, photophobia and tearing. Chronic AU may be asymptomatic or present with mild blurred vision. Concomitant scleritis and posterior uveitis need to be excluded. Elevated intraocular pressure or iris atrophy may also suggest a diagnosis of viral AU. The most common viruses associated with AU include HSV, VZV and CMV (Chan and Chee, 2019).

Cytomegalovirus

Over 85% of Asian populations are seropositive for CMV compared to 51.5–54.4% in the West (Chee and Jap, 2010; Lin, 2015). CMV AU presents mainly in males in their fourth to fifth decade of life, mostly affecting the anterior segment with a variety of clinical features (Lin, 2015; Chan and Chee, 2019; Pleyer and Chee, 2015; Touhami et al., 2018).

CMV AU may follow two courses: a Posner-Schlossman Syndrome (PPSS) pattern of recurrent acute attacks or chronic anterior uveitis, the Fuchs uveitis syndrome (FUS) like pattern. In acute AU, patients typically present with recurrent, acute evanescent episodes of mild unilateral AU and a small number of granulomatous keratic precipitates (KPs) (typically 1–5 KPs) and markedly elevated IOP (up to 50 mmHg) causing mild ocular discomfort, mild blurred vision and haloes (Chan and Chee, 2019; Bowling, 2016; Lin, 2015). Clinical features include low-grade anterior chamber inflammation with no or minimal flare, diffuse iris stromal atrophy, a round pupil with no posterior synechiae and a normal posterior segment (Chan and Chee, 2019; Pleyer and Chee, 2015). Common clinical features are summarized in Table 2 (Fig. 5).

Table 2 Clinical features of anterior uveitis caused by herpes simplex virus, varicella-zoster virus and cytomegalovirus (Chan and Chee, 2019; Pleyer and Chee, 2015).

<i>CMV acute—PPSS like pattern</i>	<i>CMV Chronic-FUS like pattern</i>	<i>HSV</i>	<i>VZV</i>
• Male patients • 20–50 years • Mild conjunctival injection • Very high IOP • Endotheliitis • Single or few coin-shaped KPs • Linear KPs • Minimal AC activity • Diffuse iris atrophy (43%)	• Male patients • Asian population • 40–60 years • Mild conjunctival injection • Very high IOP • Fine, white, stellate diffusely distributed KPs • Mild AC activity • Diffuse iris atrophy (60%) • Cataract (>80%)	• <50 years • No gender predilection • Moderate to severe conjunctival injection • IOP with acute spikes • Vesicles in border eyelids • Dendrites or stromal keratitis • Small-medium size KPs • Moderate AC activity • Sectoral iris atrophy • Posterior synechiae • Vitritis (43%)	• >60 years • No gender predilection • Moderate to severe conjunctival injection • IOP with acute spikes • Vesicular rash dermatome CN V1 • Pseudodendrites or nummular keratitis • Small-medium size KPs • Severe AC activity • Sectoral iris atrophy • Posterior synechiae • Vitritis (83%)

**Fig. 5** These photographs illustrate extensive iris atrophy (arrow) in varicella zoster virus uveitis on a slit-lamp (left) and a retro-illuminated image (right).

In chronic AU, patients present with a chronic unilateral low-grade inflammatory disorder with raised intraocular pressure, resembling Fuchs uveitis syndrome (FUS) (Touhami et al., 2018). It is less aggressive than the other uveitides with majority of patients asymptomatic for a long period of time. It mostly presents in males in the third or fourth decade of life from Asian populations (Japan, Taiwan and Singapore). It presents with minimal ocular discomfort, blurred vision and variably elevated IOP up to 50 mmHg. Clinical features include mild-to-moderate anterior chamber activity, no ciliary injection, fine stellate uniformly white distributed KPs over the entire endothelium. Other signs include late posterior subcapsular cataract in 81% patients and diffuse iris stromal atrophy and fragile vasculature (Chan and Chee, 2019; Bowling, 2016; Pleyer and Chee, 2015). Common clinical features are summarized in Table 2. In European patients, there are fewer and small pigmented KPs located inferiorly, minimal anterior chamber inflammation with posterior subcapsular cataract developing late in the disease in 75% of eyes (Chan and Chee, 2019).

Corneal endotheliitis presents with KPs, stromal edema and Descemet folds, isolated or associated with AU. These findings may be localized or manifest similarly to bullous keratopathy with severe corneal edema and elevated intraocular pressure. Immune ring formation can also be associated with CMV endotheliitis (Chan and Chee, 2019).

Herpes simplex virus

Herpes simplex virus type 1 mainly causes this condition affecting both genders in their fourth and fifth decade of life. It occurs due to reactivation of the primary disease (Chan and Chee, 2019; Pleyer and Chee, 2015). HSV/VZV accounted for 8% of uveitis cases in the Pacific Ocular Inflammation Study (Lin, 2015; Acharya et al., 2013). The patient may have a past history of fever or blisters (Chan and Chee, 2019). The infection may manifest in the periocular skin, in the cornea or only in the uvea (Pleyer and Chee, 2015).

Clinical features include: diffuse small to medium-size, stellate or granulomatous KPs, elevated intraocular pressure, sector iris atrophy, moderate anterior chamber activity with cells and flare (Valerio and Lin, 2019; Bowling, 2016; Chan and Chee, 2019; Lin, 2015). Posterior synechiae develop in a third of cases and anterior vitritis in nearly half of involved eyes. IOP is high due to

trabeculitis (Chan and Chee, 2019). Sectorial iridoplegia and localized flattening of the pupil border in the affected area with poor reaction to light may be present. After the episode resolves, the pigment epithelium is destroyed resulting in patchy or sectorial iris atrophy with transillumination defects (Chan and Chee, 2019). Common clinical features are summarized in Table 2.

Corneal scars and hypoesthesia may be present as result of previous epithelial or stromal keratitis (Chan and Chee, 2019; Lin, 2015). HSV uveitis commonly occurs in eyes with active or prior keratitis and the uveitis correlates with the severity of keratitis. Chronic stromal or endothelial disease are associated to more severe uveitis (Chan and Chee, 2019).

Varicella zoster virus

Varicella zoster virus is latent in neural sensory ganglia after primary infection and reactivates when immunity wanes usually in older patients (immunosenescence) or in an immunocompromised patient (Chan and Chee, 2019; Pleyer and Chee, 2015). VZV anterior uveitis may present months after the rash associated with HZO resolves or rarely without skin involvement (Zoster sine herpette; Chan and Chee, 2019). In patients over age 60, unilateral AU in association with sectoral iris atrophy with transillumination defects, and no evidence of prior or concurrent epithelial or stromal keratitis is a common presentation (Pleyer and Chee, 2015). Common clinical features are summarized in Table 2; Fig. 6.

Diagnostic tests

Aqueous humor analysis is a useful and common method to determine viral etiology and severity of the disease as the diagnosis may not be possible based only on the clinical features. However, several taps maybe needed as false negatives are frequent due to prior or current antiviral therapy (Chan and Chee, 2019; Valerio and Lin, 2019; Lin, 2015; Pleyer and Chee, 2015). An anterior chamber tap is performed under aseptic technique and aqueous humor is sent for PCR analysis.

Polymerase chain reaction (PCR) can detect minimal amounts of viral DNA and enable rapid confirmation of the diagnosis (Chan and Chee, 2019; Lin, 2015). The aqueous tap should be done during the IOP spike, prior to initiating therapy especially when suspecting CMV (Lin, 2015). Negative PCR does not exclude viral etiology. It may be due to low intraocular viral load, limited volume of aqueous humor sample, a short-lived phase of DNA release that may have been missed during the time of aqueous sampling due to delay in presentation or testing. A positive result may only be obtained after repeated aqueous taps. PCR may give a false positive by detecting CMV DNA from latent virus in leucocytes present in the anterior chamber during inflammation (Chan and Chee, 2019).

PCR tends to be positive at the outset and/or during early reactivation, but viral DNA levels may fall below the detection limit in later stages of the disease. HSV-VZV commonly present during the acute phase when the viral load is higher and are frequently detected by PCR (Chan and Chee, 2019).

Treatment

The mainstay of treatment is a combination of topical and/or oral antivirals, topical corticosteroids, topical nonsteroidal anti-inflammatory drugs (NSAIDs) and IOP-lowering agents if needed (Pleyer and Chee, 2015; Fung et al., 2020).

For CMV, ganciclovir topical gel 0.15%, five times daily is the preferred antiviral therapy due to its efficacy, affordability and safety (Pleyer and Chee, 2015; Chee and Jap, 2010). Topical steroids must be given if there is severe inflammation (prednisolone acetate 1% twice daily). They have less systemic side effects compared to periocular or systemic steroids agents (Fung et al., 2020). This may be tapered and replaced by NSAIDS ketorolac tromethamine 0.4%, four times daily (Pleyer and Chee, 2015). Recurrences tend to present even after successful 3-month treatments. Some patients are unable to come off the therapy and may require topical ganciclovir, and low dose of topical steroids or NSAIDS with or without antiglaucoma medications indefinitely.

For HSV and HZV uveitis, antiviral agents including oral acyclovir, valacyclovir or famciclovir are used along with topical steroids for example prednisolone acetate 1% four times daily, and a topical cycloplegic, atropine 1% twice daily, if anterior chamber inflammation exceeds of 1+ cell. This is to reduce pain and prevent posterior synechiae (Pleyer and Chee, 2015) (See Table 3). Topical corticosteroids must be avoided if epithelial HSK is present. Furthermore, IOP must be treated as needed (Lin, 2015;

Fig. 6 These photographs illustrate a localized iris atrophy (arrow) in herpes simplex uveitis on a slit-lamp examination (left) and a retro-illuminated image (right).

Table 3 Treatment of anterior and posterior uveitis (Chee and Jap, 2010; Aizman et al., 2007; Lee et al., 2017; Wu et al., 2019; Baltinas et al., 2018; Valerio and Lin, 2019; Schoenberger et al., 2017; Stryjewski et al., 2018; Pleyer and Chee, 2015; Scott et al., 2002; Tseng et al., 2015).

Indication	Dosage
AAU	HSV/VZV <i>Therapeutic:</i> • ACV 400–800 mg, 5 times daily for 4–6 weeks • VLC 500 mg⁻¹ g, TDS for 6 weeks • FCV 250–500 mg TDS <i>Prophylaxis:</i> • ACV 400 mg BD-TDS • VLC 500 mg⁻¹ g BD • FCV 250–500 mg BD CMV Topical gel GCV: 0.15%, apply five times daily for 3 months
ARN	• IV ACV 10–15 mg/kg TDS for 5–14 days FOLLOWED BY ACV 400–800 mg, five times daily for 6–12 weeks • VLC 2 g TDS for 6 weeks • Intravitreal injection Foscarnet 2.4 mg/0.1 mL
PORN	• IV ACV 10–15 mg/kg TDS PLUS • IV foscarnet 60 mg/kg three times or 90 mg/kg twice daily for 2 weeks • IV GCV 5 mg/kg twice daily PLUS • IV foscarnet, 60 mg/kg three times or 90 mg/kg twice daily for 2 weeks, FOLLOWED BY oral valganciclovir, 900 mg once daily PLUS • IV foscarnet 90–120 mg/kg/day until healing is achieved • IV GCV 5 mg/kg twice daily PLUS • IV ACV 10–15 mg/kg TDS • Intravitreal GCV 2 mg/0.05 mL PLUS • IV ACV 10–15 mg/kg TDS OR • IV foscarnet 60 mg/kg three times or 90 mg/kg twice daily • Intravitreal GCV 2 mg/0.05 mL PLUS • Intravitreal foscarnet 1.2 mg/0.05 mL, three times weekly for 2 weeks, FOLLOWED BY maintenance injections once or twice weekly until retinitis is stabilized
CMV retinitis	• IV GCV 5 mg/kg, TDS weekly as induction dose for up to 3 weeks FOLLOWED BY 5 mg/kg as a maintenance dose • Valganciclovir 900 mg BD for 3 weeks as induction therapy; then 450 mgs BD as maintenance dose NB. Dose adjusted depending on renal function

Key: AU, anterior uveitis; ARN, anterior retinal necrosis; BD, twice daily; CMV, cytomegalovirus; FCV, famciclovir; GCV, ganciclovir; HSV, herpes simplex virus; IV, intravenous; PORN, progressive outer retinal necrosis; TDS, three times daily; VZV, varicella zoster virus.

Bowling, 2016). When treating VZV uveitis, systemic antivirals should be commenced within 72 h of rash onset (Pleyer and Chee, 2015). Acute trabeculitis responds very well to topical corticosteroids even without antihypertensive medication. However, inadequate antiviral therapy can lead to recurrent episodes and risk of glaucoma development (Valerio and Lin, 2019) (Table 3).

Posterior uveitis

Posterior uveitis refers to the inflammation of the posterior uveal tract formed by the retina and the choroid (Lee et al., 2017). Studies from United States (Merrill et al., 1997; Rodriguez et al., 1996; McCannel et al., 1996; Henderly et al., 1987); Europe (Pivetti-Pezzi et al., 1996; Smit et al., 1993); Australia and New Zealand (Zagora et al., 2017; Wakefield et al., 1986; Hart et al., 2019; Wong et al., 2017); and Asia (Al Dhibi et al., 2017; Al-Shakarchi, 2014; Rahman et al., 2018; Amin et al., 2019; Chen et al., 2017; Abaño et al., 2017; Pathanapitoon et al., 2008) have reported the prevalence of posterior uveitis from 5% to 46%. Most cases are idiopathic or inflammatory in origin (Tsirouki et al., 2018), however the proportion of infectious cases can fluctuate from about 40% reported in studies from Australia (Zagora et al., 2017) and New Zealand (Wong et al., 2017) to about 80% reported in a study from Iran (Kianersi et al., 2015; Lee et al., 2017).

The latent-reactivation cycle of HSV, VZV, CMV depends on the interaction with the host immune system and external factors. Depressed cell-mediated immunity can lead to reactivation of latent virus causing the disease. HSV and VZV retinitis occur both in immunocompetent and immunocompromised patients; whilst CMV retinitis only occurs in immunocompromised patients. Progressive outer retinal necrosis (PORN), a rare hyperacute form of VZV retinitis is only seen in immunocompromised patients.

Symptoms of posterior uveitis include: decreased visual acuity, visual field defects, floaters, photopsia, photophobia and occasionally pain. Signs include: conjunctival injection, variable anterior uveitis, and keratic precipitates, raised IOP, vitreous cellular infiltrate, vitreous haze and a wide range of retinal and choroidal changes. Important clinical features include: macula edema, optic disk swelling focal or diffuse retinal and choroidal lesions, and retinal vasculitis (Lee et al., 2017).

Diagnosis of posterior uveitis is based on clinical assessment by a detailed history, thorough ocular examination of each eye and a careful review of systems. Multi-modal imaging such as wide field retinal imaging, digital fundus photography, fundus autofluorescence, fundus fluorescein angiography, indocyanine green angiography and optical coherence tomography can be used for diagnosis and monitoring response to treatment. The tetraplex PCR analysis for HSV, VZV and CMV can confirm the causing organism in 59–100% of cases with a PCR sensitivity of 80.9–84% and a specificity of 97.4–100% (Lee et al., 2017).

Treatment of infectious posterior uveitis includes: appropriate systemic or intravitreal anti-microbials which are often combined with oral corticosteroid therapy. Serious complications include cataracts, band keratopathy, uveitic glaucoma, cystoid macular edema and retinal detachment leading to blindness (Lee et al., 2017).

Acute retinal necrosis

Acute retinal necrosis (ARN) syndrome is a sudden onset, vision threatening, rapidly progressive retinal infection characterized by circumferentially spreading areas of retinal necrosis, retinal vasculitis, optic neuropathy and intraocular inflammation. ARN is rare with an annual incidence of 0.5–0.63 new cases per million population according to British studies (Cochrane et al., 2012; Muthiah et al., 2007; Schoenberger et al., 2017). It is caused by VZV, HSV-1 or HSV-2 and occurs in both immunocompetent and immunosuppressed patients (Pleyer and Chee, 2015; Valerio and Lin, 2019; Aizman et al., 2007; Lee et al., 2017; Chong et al., 2009). In many parts of the world solid organ transplantation is now the commonest cause of immunocompromised rather than HIV infection. CMV is the commonest cause of retinitis in patients with acquired immunodeficiency syndrome (Dabil et al., 2001). Clinically it can sometimes be difficult to differentiate CMV infection from other herpetic retinitis in immunocompromised patients. Whenever possible it is best to confirm the diagnosis by PCR testing.

VZV and HSV-1 is more likely to be found in middle aged and old patients, and HSV-2 in children and young adults (Lin, 2015; Pleyer and Chee, 2015; Cochrane et al., 2012). VZV infections have poor prognosis needing more aggressive antiviral treatments. This may be explained by viral features and/or age-related changes. Retinitis occurs from reactivation of latent virus; however, the exact pathogenesis remains unclear (Pleyer and Chee, 2015).

Early identification of the causative virus is important to guide treatment (Dabil et al., 2001). ARN presents with a rapidly progressive pan-uveitis with unilateral vision loss, photophobia, floaters and pain with up to one third of cases progressing to bilateral disease (Lin, 2015). The infection spreads rapidly over hours to several days. The diagnosis is typically made by clinical examination and confirmed by PCR from vitreous or aqueous. Standard diagnostic criteria published by the American Uveitis Society include (1) >1 foci of retinal necrosis with discrete borders in the peripheral retina, (2) rapid circumferential progression of necrosis in the absence of antiviral therapy, (3) evidence of occlusive vasculitis and arteriolar involvement, and (4) prominent inflammation in the vitreous and anterior chambers (Valerio and Lin, 2019; Pleyer and Chee, 2015; Lee et al., 2017; Aizman et al., 2007; Lin, 2015). The risk of a second eye involvement may be reduced by systemic antiviral therapy. Second eye involvement most frequently develops within 6 weeks of the initial infection but may long delayed. The progression of retinitis is usually controlled within 2–4 weeks. Once the acute episode is controlled, severe retinal atrophy develops with well-demarcated diaphanous lesion borders predisposing to retinal breaks. Vitreous organization may lead to proliferative vitreoretinopathy which further increases the likelihood of retinal breaks and retinal detachment which occurs in up to 70% of ARN affected eyes. Other complications include: vitreous haze and membranes, macular edema, optic atrophy, epiretinal membrane formation and viral relapse following antiviral cessation (Pleyer and Chee, 2015) Fig. 7.

Generally, the diagnosis of ARN is made by clinical examination. Laboratory tests can assist in the diagnosis in less typical cases. Polymerase chain reaction test is the standard method to identify viral DNA from small aqueous or vitreous samples (Schoenberger et al., 2017). Several studies have reported PCR testing of aqueous and vitreous samples. Only one study found a significant difference when comparing aqueous and vitreous samples (93% positive for vitreous samples and 46% for aqueous samples). Other studies found no significant differences between both type of samples. There is insufficient evidence to recommend one type of sample over the other (Schoenberger et al., 2017; Wu et al., 2019).

Antiviral treatment must be commenced as soon as clinical diagnosis is made (Lee et al., 2017; Schoenberger et al., 2017). There are no randomized clinical trials to establish standard therapies. However, the standard therapy remains as intravenous acyclovir 10–15 mg/kg, three times daily at least for 7 days; or 1500 mg/m² daily for 5–10 days, followed by oral acyclovir 800 mg, five times daily for 6–12 weeks (Aizman et al., 2007; Pleyer and Chee, 2015; Valerio and Lin, 2019; Lee et al., 2017). Side effects of the intravenous treatment include nausea, vomiting, diarrhoea, headache, photosensitivity, rash, myelosuppression, reversible rise in the serum creatinine levels, urinary calculi, elevation in liver function tests, and central nervous system toxicity such as lethargy, delirium and seizures (Wu et al., 2019; Aizman et al., 2007). Studies have shown that valacyclovir 2 g, four times daily can be used instead of the intravenous acyclovir (Valerio and Lin, 2019; Baltinas et al., 2018). Valacyclovir is a well-tolerated medication with few side effects. For initial non-responders or patients with retinitis lesions threatening the optic nerve or the macula, adjunctive intravitreal foscarnet therapy can be used (Aizman et al., 2007; Pleyer and Chee, 2015; Valerio and Lin, 2019; Stryjewski et al., 2018; Wu et al., 2019). See Table 3 for antiviral dosages.

Retinal detachment occurs in up to 75% of patients (Lee et al., 2017; Lin, 2015). Baltinas et al. found that patients treated with oral valacyclovir (66%) or IV acyclovir (62%) had similar risk of developing retinal detachment usually approximately 60 days after presentation (Baltinas et al., 2018; Wu et al., 2019). Prophylactic barrier laser should be done within 6 weeks of diagnosis to allow adequate chorioretinal adhesion before vitreous detachment. Baltinas et al. reported that the prophylactic barrier was given to a third of patients within a week of the diagnosis. This procedure did not reduce the risk of retinal detachment regardless the treatment given to the patients (Baltinas et al., 2018). Other complications include: cataract development, epiretinal membrane formation, recurrent AAU and cystoid macular edema, hypotony/phthisis and reactivation of the infection either in the same eye or in the fellow eye (Baltinas et al., 2018).

Fig. 7 (A) This photograph illustrates an early acute retinal necrosis on the left eye with multiple small foci of peripheral retinitis. (B–D) These photographs illustrate 24 h later: a peripheral retinitis much worse, swollen disk from optic neuropathy and hazy media from severe inflammation.

Oral prednisone 40–80 mg daily can be added to the treatment in case of severe inflammation for example in severe vitritis, serous retinal detachment, or vasculitis (Wu et al., 2019; Lee et al., 2017). Topical corticosteroids may decrease anterior vitritis and cystoid macular edema (Wu et al., 2019).

Progressive outer retinal necrosis

Progressive outer retinal necrosis is a very rapidly progressive bilateral devastating form of ARN only seen in very immunocompromised patients, for example in AIDS patients with low CD4⁺ T lymphocyte counts (<50 cells/ μ L) or in solid organ transplant patients on very intense immunosuppressive therapy (Lee et al., 2017; Wu et al., 2019). VZV is the causative organism of PORN (Lee et al., 2017; Wu et al., 2019). This condition presents with acute rapidly progressive blurred vision, visual field loss, without pain or photophobia. There is extensive multifocal necrotizing retinitis at the posterior pole that rapidly spreads to the retinal periphery. The typical macular lesion is a white, necrotic, parafoveal opacification with a central cherry red spot (Lee et al., 2017; Wu et al., 2019) Fig. 8.

Diagnosis of PORN is based on a diagnostic criteria proposed by Engstrom et al. and PCR analysis of intraocular fluids for VZV (Lee et al., 2017; Wu et al., 2019). The diagnostic criteria include (1) multifocal, deep retinal opacification without granular borders, (2) lesions may be confluent, (3) peripheral lesions with or without macular lesions, (4) very rapid progression, (5) inconsistent direction of disease spread, (6) no vascular inflammation, (7) none or minimal intraocular inflammation (Engstrom Jr. et al., 1994; Wu et al., 2019).

Aggressive systemic and intravitreal antiviral therapy must be commenced early, as PORN progresses rapidly, to prevent progression of retinitis, induce remission, prevent the infection in the contralateral eye and preserve useful vision (Lee et al., 2017). Systemic antiviral agents include intravenous foscarnet 24 mg/mL three times daily, intravenous ganciclovir 5 mg/kg/24 h, and intravenous acyclovir (Lee et al., 2017). A combination of antiviral agents leads to better visual outcomes. The following combination are recommended: intravenous acyclovir plus foscarnet, intravenous ganciclovir plus intravenous foscarnet, intravenous ganciclovir and intravenous acyclovir, intravitreal ganciclovir plus intravenous acyclovir, or intravitreal ganciclovir plus intravitreal foscarnet (Lee et al., 2017; Wu et al., 2019; Scott et al., 2002). When patients respond to treatment oral valacyclovir 1 g, three times daily, valganciclovir or famciclovir is given for maintenance. Oral prednisolone 40 mg/day may be given to reduce intraocular inflammation, for example vitritis (Lee et al., 2017).

Panretinal photocoagulation can be considered but is not useful in preventing retinal detachment. Retinal detachment may be treated with vitrectomy with silicon oil tamponade (Lee et al., 2017). Two-thirds of patients with PORN progress to no light perception. Generally, PORN has poorer visual outcomes than ARN due to its poor respond to antiviral therapy. Complications of PORN include retinal detachment in 70% cases, optic disk edema or atrophy, vitreous hemorrhage, macular edema and infection in the fellow eye (Lee et al., 2017).

Fig. 8 These photographs illustrate progressive outer retinal necrosis (PORN) with widespread retinal lesions, posterior pole involved and typical macular retinitis.

Cytomegalovirus retinitis

CMV retinitis is an opportunistic infection in severe immunocompromised patients (Lee et al., 2017; Wu et al., 2019). During the last century, CMV retinitis occurred mainly in severe immunocompromised AIDS patients with CD4⁺ counts below 100 cells/ μ L. Currently, susceptible patients include those on immunosuppression after solid-organ transplantation, malignancy, hematopoietic stem cell transplantation or those receiving immunosuppressive medication for other reasons (Wu et al., 2019; Lee et al., 2017). Up to 85% of AIDS patients with CD4⁺ counts less than 50 cells/ μ L present CMV retinitis. CMV retinitis can rarely occur in seemingly immunocompetent patients. Such patients are mild to moderately immunocompromised from advanced age, diabetes mellitus, corticosteroid or noncytotoxic immunosuppressive medication use. CMV retinitis can present at any age, with an unilateral presentation progressing to the contralateral eye in 20% of cases within 6 months (Lee et al., 2017).

CMV retinitis is asymptomatic in up to 50% of patients. Symptoms include: blurred vision, floaters, visual field loss and ocular discomfort (Lee et al., 2017). Clinical features include: mild anterior segment inflammation keratic precipitates, anterior chamber cells, and minimal vitritis (Lee et al., 2017; Wu et al., 2019). The characteristic fundus clinical feature is a single focus of full thickness yellow-white necrotizing granular retinitis in the peripheral retina with a perivascular distribution which expands centrifugally (Lee et al., 2017). In other patients with CMV retinitis there is more overlying vitritis and the involved retina has a characteristic yellowish white color and there is associated retinal hemorrhages and vasculitis. The appearance is often described as “pizza retinitis” (lesion appearance similar to mozzarella cheese and tomato sauce) There can be extensive vascular occlusion and severe intraocular inflammation widespread necrotizing retinitis (Wu et al., 2019) Fig. 9.

The diagnosis of CMV retinitis is made by indirect ophthalmoscopy with documentation on digital fundal photography and supporting clinical history, laboratory and positive CMV PCR in intraocular fluid samples (Lee et al., 2017; Wu et al., 2019).

The treatment of CMV retinitis consists of reversing the immunodeficiency and addressing the direct damage to the retina (Wu et al., 2019; Lee et al., 2017). In HIV/AIDS patients, combination anti-retroviral therapy must be initiated or optimized if the CD4⁺ count remains low despite antiretroviral therapy (Lee et al., 2017). CMV retinitis is often a manifestation of systemic CMV infection. Peripheral blood branched chain CMV PCR at diagnosis and during follow up to determine the systemic viral load is useful to document the response to treatment. It is important to exclude sub-clinical infection in other organ systems such as the gastrointestinal tract, liver and lungs (Wu et al., 2019). In HIV patients, an increase in CD4⁺ T-cells over 200 cells/ μ L for more than 3–6 months is considered an acceptable recovery with reduced risk of CMV reactivation. In non-CD4⁺ specific immunosuppression or ongoing systemic immunosuppression to control autoimmune conditions, ophthalmologists need to work closely with other physicians to determine appropriate management of the systemic condition and the retinitis (Wu et al., 2019).

Antiviral agents including ganciclovir, valganciclovir and foscarnet are used to treat CMV infection (Lee et al., 2017). First-line therapy is intravenous ganciclovir or its oral prodrug valganciclovir which block viral thymidine kinases (See antiviral dosages in Table 3). In cases with resistance (UL97 mutations) or inability to tolerate ganciclovir, intravenous foscarnet which inhibits CMV DNZA polymerase is recommended. Intravitreal foscarnet and ganciclovir can also be used when clinically indicated for posterior pole involvement or very extensive retinitis. A typical intravenous regimen may be three times weekly as induction, reducing to twice weekly until retinitis is controlled and immune function is improved. Systemic antivirals are used to protect the contralateral eye. Complications include extension of retinitis, involvement of contralateral eye, epiretinal membrane formation, retinal neovascularization, posterior subcapsular cataracts, phthisis, optic atrophy and rhegmatogenous retinal detachment in up to 30% of cases (Lee et al., 2017).

Fig. 9 This photograph illustrates a typical CMV retinitis involving the retinal periphery.

A fungal infection of the eye is a significant cause of vision impairment and blindness (Thomas, 2003; Spadea and Giannico, 2019). It affects mainly the cornea but other parts of eye such as the orbit, lids, conjunctiva, sclera and the lacrimal system and internal structures can also be involved (Thomas, 2003; Spadea and Giannico, 2019; Kalkanci and Ozdek, 2011). Fungi infrequently cause infection in intact ocular tissues. Minimal disruption of the corneal epithelium can predispose to fungal keratitis. Numerous fungal species have been associated with ocular infections. Thomas et al. in their review grouped fungal species into hyaline filamentous fungi, dematiaceous fungi, yeasts and zygomycetes, thermally dimorphic fungi and other with uncertain classification (*Pythium insidiosum*, *Rhinosporidium seeberi*, and *Pneumocystis carinii*) (Thomas, 2003).

Hyaline filamentous fungi include *Fusarium*, *Aspergillus*, *Scedosporium*, *Paecilomyces* and *Acremonium* species. *Fusarium* species are a saprobic fungus causing infections in plants and immunocompromised patients. *Aspergillus* species thrive in substrates like corn, decaying vegetation and soil and are commonly found in hospital air (Thomas, 2003). *Scedosporium* species has been found in soil, sewage, polluted water and manure from farm animals. This fungus has been associated with severe ocular infection following trauma by vegetative material, contact with polluted water and immunosuppression. *Paecilomyces* species are found in soil and decaying vegetation. They may also contaminate sterile solutions and culture media. *Acremonium* species is also found in soil, decaying vegetation and the air (Thomas, 2003).

Dematiaceous fungi include species such as *Bipolaris*, *Curvularia*, *Exophiala*, *Exserohilum* and *Lasiodiplodia theobromae*. The dark pigmentation of their hyphae is the common denominator among them. They are a common cause of keratitis after *Fusarium* and *Aspergillus*. *Lasiodiplodia theobromae* is prevalent in tropical regions in corn, yams, citrus and banana plants (Thomas, 2003).

Most yeasts associated with keratitis are from the *Candida* species, especially *Candida albicans*. This occurs in patients with a history of immunosuppression, diabetes mellitus, ocular disease (lid abnormalities or dry eye) or use of topical corticosteroids (Thomas, 2003; Qiao et al., 2020; Klotz et al., 2000). *Cryptococcus* species is associated with immunocompromised patients (Thomas, 2003). Zygomycetes include *Rhizopus* spp., *Mucor* spp. *Rhizomucor* spp. and *Absidia* spp. They can cause rhino-orbitocerebral zygomycosis and keratitis (Thomas, 2003; Klotz et al., 2000; Mukherjee et al., 2016).

Thermally dimorphic fungi include *Paracoccidioides brasiliensis*, *Coccidioides immitis*, *Blastomyces dermatitidis*, and *Histoplasma capsulatum*. These fungi are found in soil and decaying vegetation in endemic sites in United States, Central and South America. They cause severe and chronic disease affecting skin, lungs and lymphoid organs. Ocular manifestations occur after reactivation of the disease and may manifest as eyelid lesions, orbital disease, keratitis and endophthalmitis (Thomas, 2003; Slowik et al., 2015).

Orbital infections

Infections of the orbit usually occur as secondary infections from nearby structures including paranasal sinuses, skin and the nasopharyngeal cavity (Klotz et al., 2000). The inflammatory conditions affecting the eyelids and the orbit are classified into preseptal (periorbital) and postseptal (orbital) (Kalkanci and Ozdek, 2011).

Orbital cellulitis is mainly caused by bacteria. Fungal and viral infections rarely occur. Fungal orbital cellulitis is seen in patients with uncontrolled diabetes mellitus or other immunodeficiencies. Orbital cellulitis is always invasive. Causal organisms include Zygomycetes, *Aspergillus* and less common *Blastomyces*, *Sporothrix* spp. and *Bipolaria* spp. (Kalkanci and Ozdek, 2011; Mukherjee et al., 2016). Early diagnosis is paramount for a timely treatment.

Mucormycosis

The zygomycete, *Rhizopus oryzae* is the major culprit of the following conditions: Rhino-orbital-cerebral zygomycosis (ROCZ), rhino-orbital-cerebral mucormycosis (ROCM), zygomycosis, phycomycosis and orhyphomycosis (Klotz et al., 2000; Mukherjee et al., 2016; Thurtell et al., 2013). Other zygomycetes include *Mucor ramosissimus*, *Rhizomucor pusillus*, *Absidia corymbifera* and *Apophysomyces elegans*. A zygomycetes is a filamentous fungus found in soil, decaying fruit, vegetables and animal feces. ROCZ mainly occurs in immunocompromised patients. Risk factors include patients with uncontrolled diabetes with ketoacidosis, neutropenia, patients with iron overload, intravenous drug abuse, chemotherapy, hematologic malignancy, bone marrow transplant, solid organ transplant and use of corticosteroids and immunosuppressant medications (Mukherjee et al., 2016; Thurtell et al., 2013).

Clinical features include fever, sinusitis, nasal discharge, epistaxis, orbital and periorbital edema and pain, nasal mucosal ulceration, crusting and necrosis (Mukherjee et al., 2016; Yohai et al., 1994). Ocular features include: decreased vision, proptosis, complete external ophthalmoplegia, ptosis, chemosis, internal ophthalmoplegia and corneal anesthesia (Johnson, 2000; Mukherjee et al., 2016) (Fig. 1). The orbital apex syndrome (OAS) encompasses three elements: visual loss due to optic neuropathy, ophthalmoplegia due to third, fourth and sixth cranial neuropathy, and ocular-orbital pain and/or anesthesia due to involvement of the ophthalmic division of the trigeminal nerve (Thurtell et al., 2013). Sudden blindness can occur due to central retinal artery occlusion, thrombosis of the posterior ciliary arteries, infarction of the intraorbital part of optic chiasm (Mukherjee et al., 2016; Downie et al., 1993). ROCZ can also manifest as a painless OAS without orbital cellulitis. The infection can spread to the brain via the cribriform plate and the orbital apex. Invasion of the cavernous sinus and cavernous part of the carotid artery can lead to carotid occlusion, cerebral infarction, mycotic intracranial aneurysm/hemorrhage, meningitis, mycotic abscess and death (Mukherjee et al., 2016; Bae et al., 2012; Thurtell et al., 2013).

The sequence of signs and symptom onset is important in the differential diagnosis of this condition. Generally, OAS in invasive fungal sinusitis presents with constant eye pain, followed by visual loss and ophthalmoplegia. If visual loss and ophthalmoplegia appear simultaneously, it is evident that the patient had OAS and fungal infection should be considered as a cause. If there is only eye pain, followed by visual loss, the differential diagnosis is of an acute painful optic neuropathy. Moreover, if there is eye pain followed by ophthalmoplegia, fungal infection is not one of the top causes; therefore, the diagnosis and adequate treatment are delayed if fungal infection is in fact causal (Thurtell et al., 2013). See a list of the differential diagnosis for painful OAS in Table 1. Patients with eye or facial pain are sometimes empirically treated with steroids for presumed orbital inflammatory disease or giant cell arteritis. As steroids may contribute to a devastating outcome in a patient with invasive fungal infection, a fungal infection should be suspected in a diabetic or immunocompromised patient with a painful eye even without ophthalmoplegia or visual loss (Thurtell et al., 2013).

Fig. 1 Orbital Apex Syndrome: severe chemosis (left image) and magnetic resonance imaging (right).

Table 1 Causes of orbital apex syndrome.

Type of condition	Name of condition
Inflammatory	– Sarcoidosis – Vasculitis: Churg-Strauss syndrome, Wegener's vasculitis – Giant cell arteritis – Thyroid Eye Disease – Idiopathic inflammation – Idiopathic orbital inflammation – Tolosa-Hunt syndrome – Systemic lupus erythematosus – Orbital inflammatory pseudotumor
Infectious	– Fungi: <i>Aspergillus</i> spp., <i>Rhizopus oryzae</i> – Bacteria: <i>Mycobacterium tuberculosis</i>, <i>Streptococcus</i> spp., <i>Staphylococcus</i> spp., <i>Actinomyces</i> spp., Gram-negative bacilli, anaerobes – Herpes zoster ophthalmicus
Vascular	– Carotid cavernous fistula – Carotid cavernous aneurysm – Cavernous sinus thrombosis – Sickle cell anemia
Neoplastic	– Head and neck tumors: nasopharyngeal carcinoma, adenoid cystic carcinoma, squamous cell carcinoma – Neural tumors: neurofibroma, meningioma, ciliary neurinoma, schwannoma – Metastatic lesions: lung, breast, renal cell, malignant melanoma – Hematologic: Burkitt lymphoma, non-Hodgkin lymphoma, leukemia – Perineural invasion of cutaneous malignancy
Other	– Mucocoele – Trauma: Penetrating and Nonpenetrating injury, orbital apex fracture, retained foreign body – Iatrogenic: sinonasal surgery, orbital/facial surgery

Adapted from Thurtell MJ, Chiu AL, Goolid LA et al. (2013) Neuro-ophthalmology of invasive fungal sinusitis: 14 consecutive patients and a review of the literature. *Clinical & Experimental Ophthalmology* 41(6): 567–576; Yeh S and Foroozan R (2004) Orbital apex syndrome. *Current Opinion in Ophthalmology* 15(6): 490–498.

Nasal and oral mucosa must be thoroughly examined, with samples and biopsies sent for microbiology examination and culture. Calcofluor white, Gomori's methenamine silver (GMS), hematoxylin and eosin (H and E), and periodic acid–Schiff stains are used for a prompt identification of the fungus. Sabouraud's agar without cycloheximide is used for culture. Polymerase chain reaction (PCR) test for fungal DNA can also be used for identifying the pathogen in the sample. The PCR sensitivity and specificity for zygomycetes is 100% and 92%, respectively. PCR's advantages include a fast result - within 2–4 h, compared to histopathology examination which can take up to 5 days (Hata et al., 2008).

Treatment for ROCZ must be commenced immediately without waiting for tissue confirmation of the diagnosis as there is at least 50% mortality. Consultation with an infectious disease specialist is mandatory. Management of predisposing factors, early surgical debridement, sinus drainage and antifungal agents are required. Amphotericin B is the preferred medication. The dosage is slowly increase from 0.7 to 1 mg/kg intravenous to a cumulative dose of 2–4 g over weeks to months after giving an initial test of 1 mg. Common side effects include fever, headache, myalgia, anorexia, malaise, anemia, hypokalemia, vomiting and nephrotoxicity (Mukherjee et al., 2016). Ketoconazole, clotrimazole, fluconazole, voriconazole, posaconazole and caspofungin are also alternatives to amphotericin B (Mukherjee et al., 2016). Amphotericin B in combination with flucytosine, fluconazole, itraconazole, or micafungin has been also used. Posaconazole alone was reported to be effective for *Rhizopus oryzae* (Kok et al., 2007).

Extensive surgical excision and debridement of necrotic orbital tissues and sinuses are important to decrease the fungal load. Debridement of the tissue until bleeding occurs is a good indicator of the extent of surgical resection needed. Repeated procedures may be needed. Exenteration may be life-saving and should be performed when there is an inflamed orbit with a blind eye or advanced infection of the orbit (Kalkanci and Ozdek, 2011; Mukherjee et al., 2016; Thurtell et al., 2013).

Aspergillosis

Aspergillosis is a rare infection of the orbit which affects both immunocompetent and immunosuppressed patients. *Aspergillus fumigatus*, *Aspergillus flavus*, and *Aspergillus niger* are the main causal organisms (Klotz et al., 2000). The main route of infection is from contiguous spread from sinuses. *Aspergillus fumigatus* commonly affects immunocompromised patients while *Aspergillus flavus* to immunocompetent patients (Mukherjee et al., 2016).

Predisposing factors include neutropenia (count $<1000/\text{mm}^3$), hematologic malignancy, use of corticosteroids and other immunosuppressive medications, solid organ transplantation, diabetes mellitus, prosthetic devices, trauma, environmental exposure, endemic area (Sudan), and advanced age (Mukherjee et al., 2016; Boes et al., 1994; Brown et al., 1994). Other factors include patients with burns and with occlusive dressings due to the warm and humid environment they create and loss of tissue integrity (Mukherjee et al., 2016; Warwar and Bullock, 1998).

Non-invasive aspergillosis occurs in immunocompetent patients who may harbor fungal balls or present with allergic sinusitis with the signs and symptoms of allergic rhinitis, chronic sinusitis and nasal obstruction. Orbital involvement is unusual. Invasive aspergillosis occurs in immunocompromised patients and severe neutropenia. Clinical features vary leading to misdiagnosis. Initial diagnoses include bacterial orbital cellulitis, idiopathic orbital inflammatory disease, temporal arteritis and sino-orbital malignancies. Fungal etiology must be ruled out before initiating corticosteroid therapy in a patient with painful proptosis. In immunocompromised patients, it manifests with acute proptosis with severe pain and visual loss with minimal orbital inflammation. In patients with AIDS, it presents with headache, periorbital pain, gradual proptosis and limitation of ocular movement without loss of vision over a period of weeks to months (Mukherjee et al., 2016).

Magnetic resonance imaging (MRI) provides better images of the posterior orbit, optic nerve and cavernous sinus and detects enhancement of optic nerve and cerebral dura adjacent to involved paranasal sinuses. In addition, MRI with contrast and fat suppression shows soft tissue abnormalities at the orbital apex and skull base by the time the OAS is complete and sometimes before that. These soft tissues changes show a markedly decreased signal of T2-weighted imaging. Orbital and perimaxillary fat stranding can be an early sign that the inflammatory process has spread outside the paranasal sinuses. Loss of mucosal contrast enhancement on MRI is a specific sign for invasive fungal syndrome indicating mucosal infarction (Thurtell et al., 2013) (Fig. 1). A normal brain computerized tomography (CT) cannot exclude an invasive fungal syndrome as asymmetric sinus mucosal thickening is common. Bony erosion can be seen in a paranasal sinus or orbit CT; however, it could be a sign in either an invasive fungal syndrome or in non-invasive fungal syndrome with paranasal sinus mucocoele. Evident sinusitis on CT, particularly with bony erosion, requires a nasendoscopy urgently. The causes are mostly bacterial or allergic in origin (Thurtell et al., 2013).

If there is evidence of partial OAS with extra-sinus disease on CT or on MRI, an urgent consultation with otorhinolaryngology for a biopsy of the paranasal sinuses must be sought, even if the tissues look clinically normal (Thurtell et al., 2013). Multiple biopsies must be taken from different sinuses, as fungal invasion can be patchy and in case the initial biopsy is negative. If the sinus biopsy is negative, an orbital apex biopsy must be done. This biopsy should be directed toward areas of imaging change for example contrast enhancement or fat stranding using an anterior approach (medial orbital apex biopsy via medial lid crease incision and lateral orbital apex biopsy via lateral canthotomy) or via the sinuses if the imaging change is medial (Thurtell et al., 2013). Samples should be sent for direct microscopic examination under KOH and calcofluor white; and the culture should be done in Sabouraud dextrose agar (Mukherjee et al., 2016; Klotz et al., 2000).

Fungal culture and histopathological examination of the samples is essential for diagnosis and therapy. There are no standardized guidelines; however, intravenous amphotericin B or voriconazole is preferred, followed by oral azoles. Oral itraconazole/voriconazole can be commenced after the completion of intravenous amphotericin B or as alternatives when the patient does not tolerate amphotericin B. In fact, some reports suggest that voriconazole may contribute to better outcomes at an intravenous dose of 6 mg/kg twice daily from day 1, followed by 4 mg/kg for 1 week and then oral voriconazole 200 mg twice daily for 12 weeks (Herbrecht et al., 2002; Mukherjee et al., 2016; Thurtell et al., 2013).

There is no consensus regarding surgical approach. Some authors recommend exenteration in all patients with retrobulbar or apical involvement; while others recommend less aggressive options. Debridement helps in reducing the fungal load and the penetration of the medication; but not all patients need this procedure. In some cases, prolonged systemic therapy has cured the infection without recurrence (Mukherjee et al., 2016). In immunosuppressed patients, the first step is to reverse immunosuppression and the prognosis is poor if this cannot be done. Exenteration is usually needed in severe cases (Thurtell et al., 2013). Local irrigation of amphotericin B with indwelling catheters is recommended to improve survival (Mukherjee et al., 2016).

Blepharitis

Bacteria are the common culprit of blepharitis; however, fungi infrequently can infect the superficial and deeper layers of the eyelid. *Candida* species infection presents in patients treated with broad-spectrum antibiotics or immunosuppressive medications. It manifests differently depending on the fungal species (Słowik et al., 2015). For example, *Cryptococcus* species cause ulcerative lesions while productive lesions are seen in blastomycosis (Słowik et al., 2015; Klotz et al., 2000). A nodule with a central ulcer coexisting with conjunctivitis have been reported in half of cases of paracoccidioidomycosis. This infection mainly affects agricultural male workers over 30 years of age in endemic areas. These lesions required antifungal therapy and surgical removal of the fibrotic lesions (Słowik et al., 2015).

Tear ducts

Fungal infection of the tear ducts is unusual and often accompanied by conjunctivitis. A major predisposing factor is the use of topical antibiotics or corticosteroids. Poor response to antibiotics or corticosteroids may indicate a fungal cause. About 5% of cases of lacrimal sac infection are caused by fungus. The most common fungi include *Aspergillus*, *Candida* and *Rhizopus* species. This infection is generally chronic with epiphora as a major symptom accompanied by conjunctivitis and edema of the medial canthus. Purulent discharge can appear from the lacrimal puncta of the lower eyelid when pressure is applied (Słowik et al., 2015).

Treatment includes topical natamycin, rinsing of the tear ducts and lacrimal sac with amphotericin or nystatin. If there is no response to the initial therapy, an incision of the lacrimal ducts can be performed. Silicone tube are then used to reconstruct the lacrimal ducts. Sometimes surgical procedures such as removal of the lacrimal sac or anastomosis of the lacrimal sac with the mucosa of the nasal cavity are required (Słowik et al., 2015).

Conjunctivitis

Fungal conjunctivitis is uncommon outside India. It is endemic in countries such as India, Sri Lanka and the Balkans caused by *Rhinosporidium* species. Closed reservoirs of water are a major risk factor. Fungal conjunctivitis is typically secondary to infection in the cornea, lacrimal sac and tear.

Causal organisms include *Candida*, *Aspergillus*, *Sporotrichum*, *Blastomyces*, *Coccidioides* and *Malassezia* species and dermatophytes (Słowik et al., 2015; Spadea and Giannico, 2019). The infection manifests with acute inflammation of the conjunctiva with a mucopurulent discharge (Spadea and Giannico, 2019). The lesions produce a grayish deposit on the conjunctiva with further formation of eyelid-eyeball adhesions from *Candida* infection or papular changes of a white-yellow color for *Sporotrichum* species. *Rhinosporidium* species cause pink or red inflammatory changes in the palpebral conjunctiva. Fungal conjunctivitis can cause severe complications needing intensive antifungal medications, even surgical debridement for example for *Rhinosporidium* infection (Słowik et al., 2015).

Keratitis

Fungal keratitis is a sight-threatening condition and one of the leading causes of blindness in Asia (Kalkanci and Ozdek, 2011; Watson et al., 2020; Bhartiya et al., 2007). It represents between 6% and 53% of all cases of infectious keratitis depending on the country (Klotz et al., 2000; Thomas, 2003; Kumar et al., 2010; Maharana et al., 2016; Bhartiya et al., 2007). Predisposing factors, causal organisms and outcomes vary depending on the geographic location, weather, local environment, occupation, availability of antimicrobials and gross national income (Watson et al., 2020; Kredics et al., 2015; Ali Shah et al., 2017; Garg et al., 2016). Filamentous fungi are more prevalent in developing countries with tropical climates and yeasts in developed countries with temperate climates (Qiao et al., 2020; Kumar et al., 2010). A study in India reported that 90% of fungal keratitis cases were caused by trauma while only 11–44% of fungal keratitis in USA were trauma related. In general, most the fungal keratitis cases are caused by filamentous saprophytic fungi (Klotz et al., 2000).

Predisposing factors associated with fungal keratitis include trauma with organic or vegetable matter or objects contaminated with soil, contact lens wear, history of systemic conditions, ocular surface disease and topical corticosteroid use (Kalkanci and Ozdek, 2011; Klotz et al., 2000; Kumar et al., 2010; Maharana et al., 2016; Qiao et al., 2020). Corneal trauma with vegetative matter either introduces the fungus directly into a corneal epithelial defect or the defect may become infected during the trauma. It has been associated more with agricultural or outdoor occupations (Klotz et al., 2000; Thomas, 2003).

Contact lens wear is mainly associated with *Pseudomonas aeruginosa*-related bacterial keratitis; but *Candida albicans* can also adhere to contact lenses. These organisms secrete exopolymers almost impenetrable to antibiotics. In addition, contact lens wear causes relative hypoxia of the corneal epithelium leading to changes in the cell surface glycoproteins. Microscopic defects are introduced by the contact lens wear enhancing organism adherence to the otherwise non-adherent epithelium. Fungi and bacteria adherent to contact lenses come from poor contact lens handling including during cleaning and storage of the lenses (Klotz et al., 2000).

Filamentary fungi are more associated with corneal trauma; while yeasts are related to patients with abnormal or compromised cornea, or systemic immunodeficiency for example in dry eye disease, chronic ulceration, erythema multiforme and Human Immunodeficiency Virus (Thomas, 2003; Klotz et al., 2000; Qiao et al., 2020; Galarreta et al., 2007; Ong et al., 2016). The most common filamentary fungi include *Fusarium* species, *Aspergillus* species and *Curvularia* species and the most common yeasts, *Candida albicans* and *Candida parapsilosis* (Qiao et al., 2020; Thomas, 2003; Watson et al., 2020; Maharana et al., 2016; Garg et al., 2016).

Clinical presentation

Clinical findings include coarse granular infiltration of the corneal epithelium and anterior stroma. The corneal defect appears 24–36 h after the trauma with minimal or absent host cellular infiltration. The infiltrate is often surrounded by a ring which may represent the junction of fungal hyphae and host antibodies (Klotz et al., 2000). The most common findings of culture-positive fungal keratitis include a gray or dirty-white surface, anterior chamber cellular reaction, irregular feathery margins, elevated borders, dry rough texture, satellite lesions, Descemet's folds, hypopyon, ring infiltrate, endothelial plaque, and keratic precipitates (Thomas, 2003; Maharana et al., 2016).

Fig. 2 A case of *Scedosporium prolificans* (filamentous fungal) keratitis.

Fig. 3 A case of candida keratitis in a patient on high dose oral prednisone.

In summary, common clinical features of filamentous fungi include dry elevated slough, stromal infiltrate with hyphate margins, satellite lesions and thick endothelial exudate (Fig. 2); and for yeast fungi, stromal keratitis similar to bacterial keratitis, overlying epithelial defect, discrete infiltrate, slow progression, and inferocentrally location (Thomas et al., 2012) (Fig. 3).

Diagnostic methods

Smear and culture of corneal scrapings are the preferred diagnostic methods for diagnosis of fungal keratitis (Klotz et al., 2000; Chidambaram et al., 2017; Kumar et al., 2010). A prompt suggestive diagnosis of fungal keratitis can be made if fungal hyphae or yeast cells are seen in a stained smear by direct microscopic examination (Thomas et al., 2012). About 65–75% of Gram and Giemsa stains are positive to fungal hyphae in cases of fungal keratitis (Labbé et al., 2009). Corneal scrapings should be inoculated onto plates of culture media such as blood agar and Sabourauds. Following inoculation, fungal culture media should be maintained at 22–25 degrees in a cooling incubator if available. A diagnosis of fungal keratitis can be confirmed following isolation of a fungus which takes a minimum of 48–72 h. Cultures have limited sensitivity, even lower than 25%, as it can take days or weeks to grow any organism (Kumar et al., 2010). Sometimes corneal biopsies may be needed to isolate the causing organism as filamentous fungus grow slowly in the culture (Robaei et al., 2018). Therefore, a diagnosis of fungal keratitis may be delayed after aggressive bacterial and viral keratitis failed treatments leading to poor outcomes (Klotz et al., 2000; Kalkanci and Ozdek, 2011; Brasnu et al., 2007; Thomas et al., 2012).

In vivo confocal microscopy (IVCM) is a non-invasive imaging modality to assist in diagnosing fungal keratitis. It provides high contrast in vivo images of the cornea, from the epithelium to endothelium, nerves and cells for an immediate visualization of filamentous fungi (Chidambaram et al., 2017; Brasnu et al., 2007). A third type of IVCM, the laser scanning confocal microscope Heidelberg Retinal Tomograph (HRT3) uses 670 nm red wavelength and high-resolution images, close to 1 μ m improving the sensitivity of this technique allowing the identification of yeasts, which could not be reported previously with first generation confocal microscopes (Brasnu et al., 2007; Kumar et al., 2010; Maharana et al., 2016). Sensitivity of this imaging technique for

fungal keratitis has been reported at between 80% and 94%, and specificity between 78% and 91.1% (Maharana et al., 2016; Kumar et al., 2010; Thomas et al., 2012; Kanavi et al., 2007; Labbé et al., 2009). Advantages of this imaging technique include being non-invasive, early identification of the organism, monitoring and guidance of treatment and determination of depth of infection. Limitations include the need for an experienced operator, patient collaboration, presence of motion artifacts, dense corneal infiltrates or scarring which can affect proper tissue penetration and visualization (Maharana et al., 2016; Kumar et al., 2010).

The polymerase chain reaction (PCR) test involves the enzymatic amplification of a specific sequence of DNA (Thomas, 2003). Several investigators have reported the sensitivity of the PCR ranging from 75% to 100%, and specificity from 50% to 100% for the diagnosis of fungal keratitis in relation to culture (Maharana et al., 2016; Gaudio et al., 2002; Menassa et al., 2010; Ferrer and Alió, 2011; Ghosh et al., 2007; Stone and Tan, 2014; Kim et al., 2008). It has the highest positive detection rate compared with cases with culture or smear negative results. Its advantages include that only a small sample is needed for diagnosis and the provision of prompt results - within 4–8 h, compared with cultures for which results are available between 2 and 7 days. Major disadvantages are its cost and limited availability. In some countries, it has been validated for corneal scrape samples. Its use as the only diagnostic modality in fungal keratitis is not advisable. Nevertheless, it can be used to guide early antifungal therapy while awaiting the other diagnostic test results (Maharana et al., 2016).

Management

Fungal keratitis is managed with medical therapy or surgical interventions. Medical therapy includes antifungal agents, cycloplegics to relieve anterior uveitis, and antibiotics for secondary bacterial infection (Thomas, 2003). The prognosis of fungal keratitis is generally poor due to the nonavailability of antifungal agents with good ocular penetration (Sharma et al., 2019) and the difficulty in diagnosing and choosing the adequate initial therapy (Watson et al., 2020). In fact, there is a lack of consensus for an initial therapy among specialists worldwide leading to diverse antifungal therapies (Sharma et al., 2019).

The selection of antifungal agents may depend on discussions with infectious diseases specialists, availability of antifungals or clinician's preference of medications in alignment with a Cochrane Review (FlorCruz and Evans, 2015). Topical natamycin 5% is the preferred empiric agent as it is commercially available and has been associated with better outcomes in filamentary keratitis (Watson et al., 2020; Prajna et al., 2013; Bhartiya et al., 2007; Thomas, 2003). Topical voriconazole and amphotericin B 0.15% are alternatives. Oral agents such as voriconazole, ketoconazole, itraconazole or oral fluconazole may be added (Watson et al., 2020; Thomas, 2003; Bhartiya et al., 2007); although MUTT trial 2 concluded that oral therapy was not useful (Prajna et al., 2016). Severe cases may need intracameral or intrastromal antifungals (Sharma et al., 2019).

Sharma et al. proposed and evaluated the Topical, Systemic, and Targeted Therapy (TST) protocol for the management of fungal keratitis in India, illustrated in Fig. 4 (Sharma et al., 2019). This algorithm had been used for 4 years by the time of the study.

Fig. 4 Topical, systemic and targeted therapy protocol for fungal keratitis treatment. Key: KCZ = ketoconazole, NTM = natamycin, QID = every 4 h, q1h: every hour, VCZ = voriconazole. Adapted from Sharma N, Sahay P, Maharana PK, et al. (2019) Management algorithm for fungal keratitis: The TST (Topical, Systemic, and Targeted Therapy) protocol. *Cornea* 38(2) 141–145.

Fig. 5 A large corneal grafting being performed for progressive candida keratitis that had failed medical therapy.

All cases were commenced with topical natamycin 5%, every hour for first 48 h, then every 2 h during waking hours until the epithelial defect healed and then every 4 h for 3 weeks; plus, a cycloplegic, homatropine 2%, four times daily. In case of poor response, topical voriconazole 1% was added every hour for first 48 h and then every 2 h until healed; or penetrating keratoplasty (PK) performed if there was severe corneal thinning or perforation. Systemic therapy with voriconazole or ketoconazole was recommended if the ulcer measured over 5 mm or its depth was over 50%. In case of poor response to natamycin 5% plus topical voriconazole 1%, intracameral or intrastromal antifungals were given, or a PK performed (Fig. 5). If there is a poor response after the injected antifungals, they were repeated up to 3–4 times every 72 h. If the infection worsened, a PK was performed (Sharma et al., 2019). This protocol had a success rate of 79.8% similar to other clinical trials with rates ranging from 66.7% to 73.7%. There was a low proportion of corneal perforation (6.7%) and need for PK (20.2%) (Sharma et al., 2019; Parchand et al., 2012).

Uveitis

Presumed ocular histoplasmosis syndrome

Histoplasma capsulatum infection occurs when the yeast form of this fungus is inhaled producing the pulmonary infection. This infection affects immunocompetent patients with 2000 new cases annually leading in some cases to vision impairment and blindness (Klotz et al., 2000). This infection is endemic in the Ohio and Mississippi river valleys in USA (Bowling, 2016).

More than half of patients (60%) present a bilateral disease. This syndrome is commonly asymptomatic unless macular choroidal neovascularisation (CNV) appears. The classic triad includes multiple white atrophic chorioretinal 'histo' spots about 200 µm in diameter, peripapillary atrophy without vitritis. Choroidal neovascularisation is a late manifestation present in less than 5% of patients. It is associated with a pre-existing macular histo spot. Associated subretinal fluid and hemorrhage lead to a decrease in vision. Acute chorioretinitis is mostly asymptomatic. Discrete oval-round whitish lesions <400 µm in diameter may have developed into classic punched-out histo spots have been described. Some lesions burn out and other can reactivate (Bowling, 2016; Klotz et al., 2000).

Active endophthalmitis in patients with spread of histoplasmosis secondary to AIDS or immunosuppression is associated with abundant budding yeast cells in the choroidal tissue and endothelium. Sometimes yeast cells are found in the anterior chamber structures such as iris, ciliary muscle and canal of Schlemm (Klotz et al., 2000).

This syndrome is associated with HLA-B7 and DR w2. Serological testing would be helpful but is only positive when systemic mycosis is present. Fluorescein angiography (FA) and optical coherence tomography (OCT) when CNV is suspected (Bowling, 2016).

Spontaneous regression of CNV may occur but without treatment 60% of eye with CNV would have a final visual acuity of less than 6/60. Treatment includes intravitreal anti-vascular endothelial growth factor (VEGF) injection for CNV (Bowling, 2016).

Endophthalmitis

Endogenous endophthalmitis refers to the infection of the interior of eye resulting from hematogenous spread of the initial infection from a distant site. Exogenous endophthalmitis occurs when the pathogen enters the eye through an ocular trauma or surgery (Kalkanci and Ozdek, 2011; Klotz et al., 2000). Most cases of endophthalmitis are exogenous. The incidence of endophthalmitis ranges from 0.03% to 1.3% after cataract surgery to up to 40% following open globe trauma. Fungal endophthalmitis accounts for 8.6–18.6% of culture-positive cases (Spadea and Giannico, 2019). Endogenous endophthalmitis mainly occurs in

immunocompromised patients (Klotz et al., 2000). Previous studies have reported that yeasts, *Candida* species and *Cryptococcus neoformans*, are the most common causal organisms, followed by molds, *Aspergillus* and *Fusarium* species (Sridhar et al., 2013; Essman et al., 1997; Binder et al., 2003).

Endogenous endophthalmitis

Candida species

Candida albicans is the most common causal organism of fungal endophthalmitis (Spadea and Giannico, 2019; Durand, 2017). It has been associated with immunocompromised patients treated for sepsis with broad spectrum antibiotics or parenteral nutrition, post-organ transplantation (Spadea and Giannico, 2019), neutropenia, intravenous drug use, a septic focus associated with a catheter, chronic lung disease or diabetes mellitus (Bowling, 2016; Klotz et al., 2000). A third of patients with systemic candidiasis develop endophthalmitis (Bowling, 2016; Lin, 2015). The initial manifestation is most commonly a unifocal or pauci-focal choroiditis, seen clinically as fluffy white choroidal lesions usually in the posterior pole (Fig. 6). The patient is asymptomatic at this stage. Symptoms will appear when the infection progresses to involve the retina and vitreous (Durand, 2017). Peripheral fundus lesions are uncommon and may cause little disturbance, in contrast central lesions or severe vitritis will manifest earlier (Bowling, 2016). Occasionally patients will present with a unifocal retinitis rather than choroidal lesions (Fig. 6). As ocular candidiasis may be asymptomatic until late in the infection and patients with candidemia are severely ill, an emergent fundus examination needs to be performed on any patient with candidemia (Durand, 2017). Vitritis presents with a creamy white, well-circumscribed cottonlike lesion involving the retina and choroid and extending into the vitreous cavity. Vitreous involvement is often a series of white fluffy lesions, the so called “string of pearls” sign (Fig. 6) (Bowling, 2016; Kalkanci and Ozdek, 2011; Lin, 2015).

Aspergillus species

Aspergillus species are the second most common cause of fungal endophthalmitis. They have been associated with immunocompromised patients, for example malignancy, diabetes mellitus, use of immunosuppressive medications, solid-organ transplantation, HIV, neutropenia, use of oral corticosteroids, central venous catheters, and intravenous drug use (Kalkanci and Ozdek, 2011; Spadea and Giannico, 2019). Clinical manifestations include eye pain, burning, foreign body sensation, tearing, hyperemia and blurred vision. On the slit lamp examination, thickened eyelid margins, conjunctival injection, grayish-white corneal stromal infiltration with fluffy margin located centrally, corneal ulcer with hypopyon, corneal satellite lesions, flare and anterior chamber cells can be found (Spadea and Giannico, 2019) (Fig. 7).

When the infection reaches the posterior segment, vitreous haze, vitritis or vitreous abscess may cause severe proliferative vitreoretinopathy, subretinal exudates and retinal detachment. Extensive fluffy white preretinal lesions with creamy white deep retinal and choroidal lesions and intraretinal hemorrhages, large wedge-shaped quadrants of pigmented chorioretinal atrophy and scarring occur as the infection is controlled (Spadea and Giannico, 2019) (Fig. 8).

Exogenous endophthalmitis

The source of this type of infection is the ocular surface or the environment. Ocular surface includes post-surgery, post-injection, keratitis-related, bleb-related or device-related), environment means post-trauma. Cataract surgery and corneal transplantation are the surgical procedures most associated with this infection. It may have a period of latency of weeks to months before it manifests. Even the infection is confined to the anterior chamber. The most common fungi associated with post-surgical procedures include

Fig. 6 Retina & vitreous “string of pearls” (left image), single retinal focus (right image).

Fig. 7 Clinical examination of a patient with *Aspergillus* endophthalmitis.

Fig. 8 Extensive fluffy white preretinal lesions with creamy white deep retinal and choroidal lesions and intraretinal hemorrhages in *Aspergillus* endophthalmitis.

yeast, especially *Candida glabrata* and *Candida formata*; while *Fusarium* species were found in post-trauma and post-keratitis cases and *Paecilomyces lilacinus* in post-surgery or contaminated sterilization solutions. Zygomycosis in the surrounding soft tissue and cryptococcal neuroretinitis may also lead to exogenous endophthalmitis (Klotz et al., 2000).

Diagnostic tests

Culture of the vitreous and/or aqueous and blood cultures assist with the diagnosis of endophthalmitis (Durand, 2017; Lin, 2015). Vitreous culture shows a high proportion of positive results (70–80%); however, molecular techniques may be used to identify the pathogen for negative cultures (Durand, 2017; Spadea and Giannico, 2019). Small samples of aqueous (0.1 ml) or vitreous (0.2–0.3 ml) may be taken for culture by needle aspiration. Some vitreous samples are ‘dry taps’ due to difficulty in aspirating the gel. In this case, some of the vitreous maybe removed via a vitrectomy in the operation room. Culture positivity rate of vitrectomy specimens is 90%, 50–70% for vitreous aspirates and 40% for aqueous aspirates (Durand, 2017).

Fluorescein angiography shows hyperfluorescence of the preretinal granuloma and the surrounding deep retinal lesions, and staining of the chorioretinal scars, focal vasculitis and leakage from the involved vessels (Spadea and Giannico, 2019).

Ultrasound examination is mandatory when fundus is not accessible for examination. Ultrasounds show dense opacities in the vitreous chamber for vitritis, thickening of the retinochoroidal layer due to subretinal exudative lesions, pre- and intraretinal hemorrhages, preretinal layering of exudates that lead to epiretinal membranes and retinal detachment (Spadea and Giannico, 2019).

Spectral domain optical coherence tomography (SD-OCT) has become a useful diagnostic method for retinal and choroidal disease. This method allows the visualization of infected structures and the detection of changes in response to treatment. Some

studies have reported different tomographic features for *Candida* species (Cho et al., 2011; Lavine and Mititelu, 2015; Adam and Rahimy, 2015) and for *Aspergillus* species (Adam and Sigler, 2014; Invernizzi et al., 2018). Invernizzi et al. identified two major patterns of chorioretinal changes, chorioretinal and intraretinal, on the OCT of their patients in a case series. Chorioretinal pattern consists of choriocapillaris alterations overlaid by retinal pigmented epithelium (RPE) disruption, full thickness retinal lesions extending from the subretinal region up to the preretinal space. A saw-tooth-shaped hyperreflective change was seen in the subretinal space adjacent to the penetrating lesion in the patients with full thickness involvement. The chorioretinal pattern illustrates the spread pathway of fungi from the choriocapillaris growing centripetally in the eyeball toward the vitreous chamber, for example in cases of *Candida* (Invernizzi et al., 2018).

The intraretinal pattern involves only the retina and the preretinal space. Invernizzi et al. reported that one third of patients in their case series showed an intraretinal pattern sparing retinal structures beyond the inner nuclear layer, the subretinal space and the choriocapillaris. In these cases, the organisms probably had entered the eye through the proper retinal vasculature contained into the inner nuclear layer, spread into the retina, the preretinal space and the vitreous chamber (Invernizzi et al., 2018). The *Candida* preference for the vitreous chamber rather than spreading within the retina or in the subretinal space is the reason for a better outcome of patients with endogenous *Candida* endophthalmitis compared to other patients with endophthalmitis caused by other fungi (Invernizzi et al., 2018).

Treatment

Patients should be co-managed by uveitis specialists, medical team and infectious disease specialists. If there is evidence of vitreous involvement or the internal limiting membrane (ILM) breached, vitreo-retina team should also be involved.

Early vitrectomy is required for lesions that have breached the ILM with vitreous seeding. Vitrectomy provides significant culture specimen, reduces fungal and antigen load, facilitates therapeutic agent penetration and clears the ocular media (Bowling, 2016; Lin, 2015). Intravitreal voriconazole may be given beforehand for example in patients too unwell for a vitrectomy or if the vitrectomy is delayed in cases of fungal lesions close to the fovea. Tap-and-inject could be considered in selected cases.

Voriconazole has good penetration when used systemically and is safer than amphotericin B as an intravitreal treatment. Intravitreal dose of voriconazole up (0.05 mg in 0.1 mL) is considered safe for the retina (Spadea and Giannico, 2019). If the diagnosis is still unclear, antibiotics may be also injected. Further intravitreal injection should be given in theaters as patients find them very distressing.

Blood tests including full blood count (FBC), electrolytes, urea, creatinine (EUC), liver function tests (LFT), C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), Treponema serology, HIV, three sets of blood tests should be ordered. Calcium and magnesium should be also ordered if the patient was prescribed systemic voriconazole and/or moxifloxacin due to possible prolongation of QT interval. HIV, hepatitis V virus (HCV), HBsAg, HBcAb tests should be ordered to patients who inject drugs and be immunized against hepatitis B virus (HBV). If a non-*Candida* fungal endophthalmitis is suspected, a serum cryptococcal antigen should be tested for. Other tests to request include urine culture, cardiac investigations such as electrocardiogram to assess conduction abnormalities and transoesophageal echocardiogram to check for colonization of valves, MRI brain, CT chest, abdomen and pelvis, in some cases).

Topical therapy includes a steroid every 2 h and atropine. Systemic treatment includes fluconazole or voriconazole as they are preferred due to the toxicity of amphotericin B (Durand, 2017). The usual starting dose for oral voriconazole is 400 mg, twice daily for the first two doses followed by 200 mg, twice daily thereafter. Monitoring levels of voriconazole is needed once the patient is discharged. If no fungus is found elsewhere in the body, oral voriconazole is given for 6 weeks.

Introduction

A parasite is an organism that lives on or lives in a host organism, obtaining nourishment and protection. The geographic location is an important determining factor in the development of parasitic infections. The prevalence depends primarily on the geographical distribution of the parasite, socioeconomic environment and immune status of the patient (Padhi et al., 2017; Malla and Goyal, 2016). These infections may originate from a large number of sources, with ingestion of contaminated water and food (i.e., freshwater fish, undercooked or raw beef, or pork) being the most common route. Other sources include blood-sucking insects, houseflies, and household pets.

Parasitic infections of the eye may be a manifestation of generalized systemic disease or a localized phenomenon. In most ocular parasitic cases the cause is by aberrant migration of the parasite in host tissues and sometimes due to direct inoculation of the eye (Padhi et al., 2017). Several parasites that usually strike other organs may inhabit the eye because it is a unique structure with an immunologically weak microenvironment. Once infection occurs it is usually treatable but causes significant ocular morbidity and mortality due to late diagnosis or misdiagnosis, often from unfamiliarity with the disease.

Parasitic infections in humans are more predominant in areas where environmental factors and poor sanitary conditions favor transmission from the animal host. In recent years, the increase in immigration and widespread international travel have facilitated the spread of certain parasitic infections from endemic to nonendemic areas. Knowledge of the type of parasites, dietary habits, sanitary measures, food and water conditions, and their prevalence in certain geographical regions may aid in diagnosing unusual symptoms in patients.

Interaction between the host and the parasite determines whether the parasite will die or spread throughout the body, and defines the location, type and extent of infection. The route of infection to humans varies with the parasitic species. There are three main classes of parasitic organisms, these include protozoans, helminths and ectoparasites. This article will review parasitic infections involving the eye.

Protozoans

Protozoa are one-cell organisms that can be free-living or parasitic in nature (Table 1). They can multiply in humans, which contributes to their survival and also permits serious infections to develop from just a single organism.

Toxoplasmosis

Toxoplasmosis is caused by an intracellular protozoan parasite known as *Toxoplasma gondii*. Approximately, one-third of the human population has been infected with the parasite (Hill and Dubey, 2002). Cats play an important role in the spread of toxoplasmosis, they become infected by eating contaminated rodents, birds or other small animals. The parasite is then passed in the cat's stool in the form of an oocyst. Infected cats can then contaminate the soil or water in the environment. These oocysts can survive in the soil for long periods (Dubey et al., 1970, 1998). Infection of human then occurs either by consumption of oocysts present in raw or

Table 1 Summary of protozoans parasitic infections with ocular involvement.

<i>Disease (causative agent)</i>	<i>Mode of transmission</i>	<i>Geographical distribution</i>	<i>Ocular pathology</i>	<i>Treatment</i>
Toxoplasmosis (<i>Toxoplasma gondii</i>)	Ingestion of raw or uncooked meat, exposure to infected cat feces, transplacental	Worldwide	Posterior uveitis, retinochoroiditis	Pyrimethamine, sulfadiazine, clindamycin, corticosteroid
Chagas disease (<i>Trypanosoma cruzi</i>)	Bite by triatomine bug, ingestion of contaminated food, blood transfusions or organ transplant, transplacental	Regions of the Americas, Europe, Africa, Eastern Mediterranean and Western Pacific	Skin lesions or palpebral edema with possible facial swelling	Benznidazole and nifurtimox
Malaria (<i>Plasmodium</i> spp.)	Bite by infected female anopheles mosquito	Africa, Central and South America, Oceania and Asia	Retinal whitening, vessel discoloration, retinal hemorrhage, optic disk edema	Artemisinin-based combination therapy
Leishmaniasis (<i>Leishmania</i> spp.)	Bite by infected female phlebotomine sandfly	Region of the Americas, Eastern Mediterranean region, Southern Europe, South-East Asia	Nodular lesions in the eyelids, trichiasis, nodular conjunctivitis, interstitial and ulcerative keratitis, dacryocystitis, episcleritis	Intralesional or systemic stibogluconate
Acanthamoebiasis (<i>Acanthamoeba</i> spp.)	Contamination of contact lenses, corneal trauma	Worldwide	Keratitis	PHMB, chlorhexidine, penetrating keratoplasty
Microsporidiosis (<i>Microsporidia</i> spp.)	Poor sanitary conditions, close contact with domestic animal hosts, topical steroid use, immunocompromised individuals and contact lenses	Worldwide	Keratoconjunctivitis, epithelial keratopathy, anterior uveitis, stromal keratitis	Albendazole, fumagillin, fluoroquinolones and voriconazole, penetrating keratoplasty

Key: *spp.*, species, *PHMB*, polyhexamethylene biguanide.

uncooked meat, exposure to infected cat feces or mother to child transmission during pregnancy (Hill and Dubey, 2002). Within days of exposure, *T. gondii* multiplies and differentiates within cells that line the human digestive tract. From there the parasite can penetrate the intestinal mucosa and reach distant organs such as the brain, eyes, liver, spleen, lymph nodes, heart, skeletal muscles and the placenta by blood and lymphatic stream (Harker et al., 2015). Dendritic cells and macrophages guide the parasite through the blood-brain barrier allowing infection of the brain and eye (Harker et al., 2015; Feustel et al., 2012).

Children and young adults (25–45 years) are affected by Toxoplasmosis which is often recurrent (Ng and McCluskey, 2002). Ocular toxoplasmosis usually manifests in immunocompromised *T. gondii* infected individuals and in neonates who acquire infection trans-placentally. Congenital ocular toxoplasmosis usually involves both eyes, whereas acquired ocular toxoplasmosis is typically unilateral (Holland, 2004). *T. gondii* is the most common cause of posterior uveitis in adults and children (Butler et al., 2013; Holland, 2003) followed by retinochoroiditis (Dupont et al., 2012). Patients with ocular toxoplasmosis typically experience floaters, reduced vision, photophobia, redness and eye pain. Hallmark clinical signs are a vitreous cellular infiltrate associated with a white retinal lesion that is typically adjacent to a pigmented chorioretinal scar (Ng and McCluskey, 2002) (Fig. 1).

Diagnosis is based on clinical features and can be supported by a serology test or polymerase chain reaction (PCR). Enzyme-linked immunosorbent assay (ELISA) can be used for the estimation of immunoglobulin G (IgG) or M (IgM) antibodies. However, serological tests have a limited role in establishing the diagnosis of ocular toxoplasmosis as they are not conclusive. Patients with positive toxoplasmosis always indicate positive for *Toxoplasma*-specific IgG, but so do infected individuals who present with no signs of ocular involvement. Hence, the use of serology testing for ocular toxoplasmosis is of low diagnostic value (Garweg et al., 2011) PCR, on the other hand, can be performed on either aqueous humor or vitreous and is both sensitive and specific (Bou et al., 1999).

The need for therapy, type of drug and duration of therapy must be tailored to the patient. An episode of ocular infection with mild inflammation and no involvement of the optic disc or macula region of the retina is self-limiting in immunocompetent patients (Ng and McCluskey, 2002). However, in immunocompromised patients, anti-parasitic medication may be required and treatment is usually required for 6–12 weeks (Padhi et al., 2017). The ideal treatment is combination drug therapy as it results in rapid resolution, whilst minimizing inflammatory damage and antibiotic resistance. The most commonly used treatment combinations are pyrimethamine, sulfadiazine and corticosteroids, or clindamycin and corticosteroid (Ng and McCluskey, 2002).

Ocular toxoplasmosis can be prevented by washing of fruits and vegetables, avoidance of cross-contamination in the kitchen with raw meat, and adequate cooking of meat to destroy any harbored cysts (Padhi et al., 2017). Pregnant women should also avoid cat litter pans as they can transmit the infection transplacentally to their unborn fetus and contraceptive precautions should be administered to women of childbearing age for 6 months following primary toxoplasmosis infection as reactivation of *T. gondii* can occur during pregnancy (Ng and McCluskey, 2002).

Chagas disease

Chagas disease is caused by *Trypanosoma cruzi*, a protozoan hemoflagellate. It was once confined to continental rural areas of the Region of the Americas (specifically Latin America). However, with increased population mobility in the last decades, most people infected live in urban settings and the disease has been increasingly detected in the United States of America, Canada, Europe, Africa, Eastern Mediterranean and Western Pacific countries (World Health Organization, 2020a). It is usually transmitted to humans via a bite from an infected blood-sucking triatomine bug. During its feed, the triatomine bug urinates or defecates while ingesting human blood, thereby excreting infective trypanosomes (Rassi and De Rezende, 2012). The parasite enters the body through mucous membranes, breaks in the skin, eyes, or mouth. Transmission can also occur by consumption of contaminated food with *T. cruzi*, blood transfusions from infected donors, passage from an infected mother to her newborn during pregnancy or childbirth, or via the transplantation of organs from infected donors (Coura and Viñas, 2010).

Fig. 1 Fundus photograph of a patient with Toxoplasmosis. Note the presence of retinitis adjacent to an old chorioretinal scar and vitritis. Image courtesy of Professor Peter McCluskey from The University of Sydney, Save Sight Institute.

There are two stages of Chagas disease, an initial acute and a chronic phase. The initial acute phase lasts for around 2 months after infection. During this phase, patients are asymptomatic or, in less than 50% of cases, individuals bitten by the triatomine bug show visible signs of skin lesions or a purplish swelling of an eyelid (World Health Organization, 2020a). Once the parasite has entered the body, the trypomastigotes circulate throughout the body with a preference for invading muscle cells, neural tissue and the reticuloendothelial system. If the initial bite is near the orbit, the patient may experience palpebral and periorbital edema. The edema is often painless and frequently accompanied by symptoms of fever, malaise and anorexia (Padhi et al., 2017). During the chronic phase, the parasites are hidden mainly in the heart and digestive muscles and can cause cardiac arrhythmias or progressive heart failure (Moncayo and Ortiz Yanine, 2006).

The diagnosis of Chagas disease is made by the detection of trypomastigotes in the blood as during the acute phase there is a large number of trypanosomes in the blood and they can be readily detected through light microscopy of blood smears (Nimir et al., 2012). In chronic Chagas disease, serological tests such as indirect fluorescent antibody (IFA) or ELISA are often performed to detect antibodies to *T. cruzi*. Although these tests are sensitive, they may yield false-positive results in patients with certain diseases, such as leishmaniasis (Santos et al., 2016).

In the acute phase, treatment with anti-trypanosome therapy (i.e., benznidazole and nifurtimox) is often effective if given early enough (World Health Organization, 2020a). The efficacy of the treatment decreases as the duration of the infection lengthens and side effects occur more frequently with old age (Padhi et al., 2017; Nimir et al., 2012).

Malaria

Malaria is a mosquito-borne infectious disease caused by parasitic protozoa of the genus *Plasmodium*. Nearly half the world's population is at risk of contracting the infection. It is endemic in Africa, Central and South America, Oceania and Asia (World Health Organization, 2019b). The natural life cycle of malaria involves cyclical infection of humans and the female anopheles mosquito. In humans, the parasite grows and multiplies first in the liver cells and then the red blood cells. The parasite then destroys the red blood cells releasing daughter parasites (i.e., merozoites), that continue the cycle by invading other red blood cells. The bite of a female anopheles mosquito, infected with the active form of the parasite (i.e., sporozoite), starts another human infection (Ashley et al., 2018).

Four species of *Plasmodium* are associated with malaria (i.e., *P. falciparum*, *P. vivax*, *P. ovale* and *P. malariae*). *P. falciparum* is associated with cerebral malaria; most of the retinal changes occur in severe cerebral malaria. Signs of malaria retinopathy include retinal whitening, vessel discoloration, retinal hemorrhage, and optic disc edema (Harding et al., 2006; Biswas et al., 1996). Retinal whitening may be seen in the macula, though some patients may only develop peripheral retinal whitening. Retinal vessels may appear orange or white, particularly in the periphery in discrete sections of the vessels or in a branching pattern (Beare et al., 2006). Intra-retinal hemorrhages are often seen with a white center and resemble Roth spots. Patients with asymptomatic to mild infections present with no too few hemorrhages, while those with severe malaria may present with numerous hemorrhages (>120 in each eye) (White et al., 2009). Optic disc edema accompanies retinal features of cerebral malaria in several cases and its presence is typically a sign of poor prognosis (Padhi et al., 2017).

Studies have shown that in cerebral malaria, retinopathy is associated with subsequent death and an increased severity of retinal signs has been related to increased risk of fatal outcome (Beare et al., 2004). It should be noted, that whilst these retinal signs indicate disease severity they do not alter the management of the disease (Nimir et al., 2012). Additionally, while retinal findings may be seen in non-cerebral malaria, they are quite rare and less severe (Lewallen et al., 2008; Beare et al., 2006, 2011).

The gold standard for diagnosing malaria is transmission electron microscope (TEM), however, the procedure is expensive, time-consuming and not feasible for routine diagnosis. Therefore, light microscopy examination of the parasite in blood smears is typically performed (Nimir et al., 2012). Although not widely available, PCR is slightly more sensitive than microscopy. However, PCR results are often not available quickly enough to be of value in establishing the diagnosis of malaria infection. Though, the technique is useful for confirming the infecting *Plasmodium* species of the malarial parasite after the diagnosis has been established; this can aid with management. Serology tests such as IFA and ELISA detect antibodies against malaria parasites, although, they do not detect current infection but rather measure past exposure. Indirect ophthalmoscopy and fluorescein angiography can also aid the diagnosis of malaria when there is retinal involvement.

The treatment of malaria is complex and dependent on the parasite species, geography and drug resistance patterns. Patients with the infection should be provided systemic antimalarial therapy, guided by local anti-malarial sensitivity and resistance patterns based on where the infection occurred. Artemisinin-based combination therapy, such as oral artemether/lumefantrine, is the most rapidly active treatment and in many situations the drug of choice. Malaria is a preventable and treatable disease, chemoprophylaxis can be administered to individuals travelling to affected areas as the drug suppresses the blood stage of the infection (World Health Organization, 2020c).

Leishmaniasis

The infection is caused by *Leishmania* species which are transmitted by the bite of infected female phlebotomine sandflies. The disease is found in parts of the region of the Americas, Eastern Mediterranean region, Southern Europe and South-East Asia (World Health Organization, 2020b). After inoculation by a sandfly, promastigotes are phagocytized by host macrophages. Within these cells, they transform into amastigotes where they replicate and may spread either systemically or cutaneously (Bates, 2007). The disease can be divided into three categories based on the organs involved: cutaneous, mucocutaneous and visceral (World Health Organization, 2020b).

Ocular involvement, commonly seen in cutaneous and mucocutaneous leishmaniasis, includes nodular lesions in the eyelids, trichiasis, nodular conjunctivitis, interstitial and ulcerative keratitis, dacryocystitis, and episcleritis (Padhi et al., 2017). Visceral leishmaniasis also known as “kala-azar,” represents the systemic forms of the disease. Ocular manifestations are typically uncommon, however patients may present with keratitis, uveitis and/or blepharoconjunctivitis (Nandy et al., 1991; Khalil et al., 2011; Pradhan et al., 2018).

Diagnosis can be confirmed by blood smears or biopsies of the lesion. Amastigotes are usually demonstrated fairly easily in ocular cases of cutaneous and mucocutaneous leishmaniasis. Other tests available include the *Leishmania* skin test, direct fluorescent antibody test, indirect hemagglutination test, ELISA, and PCR.

The treatment for leishmaniasis is dependent on the clinical syndrome, infecting *Leishmania* species, geography, organism susceptibility to treatment and immune status of the host. The most common treatment for leishmaniasis is intralosomal or systemic stibogluconate (i.e., sodium stibogluconate) (Padhi et al., 2017). Treatment of ocular leishmaniasis is more challenging. Systemic antimoniate (e.g., glucantime) and amphotericin has shown to be effective in treating ocular leishmaniasis (Reithinger et al., 2007; Nikandish et al., 2016).

Acanthamoebiasis

The genus *Acanthamoeba* contains at least 24 free-living amoebic protozoa species that are ubiquitous in nature. They are present worldwide and exist in both soil and nearly all water sources. Their life cycle exists in two forms: trophozoites (i.e., the infective form) and cysts. The trophozoite form can replicate asexually by binary fission (Alkharashi et al., 2015), while cysts remain dormant and can withstand adverse environmental conditions for years (Sriram et al., 2008).

Human ocular involvement with *Acanthamoeba* presents in the form of keratitis. *Acanthamoeba* keratitis (AK) is a rare, sight-threatening infection. Various *Acanthamoeba* species can cause chronic and progressive keratitis (i.e., corneal infection). The main predisposing risk factor is contact lens wear and corneal trauma (Carnt et al., 2018; Bharathi et al., 2007; Watson and Dart, 2012; Bartimote et al., 2019).

Patients typically present with a unilateral or paracentral epithelial defect, often with a ring-shaped peripheral infiltrate. In the early stages, patients may also present with eyelid ptosis, conjunctival hyperemia, and pseudodendrites. In the later stages, patients may present with deep stromal infiltrates, corneal perforation, satellite lesions, scleritis, and anterior uveitis with hypopyon. Clinical symptoms of the infection include severe pain, decreased vision, foreign body sensation, photophobia, tearing and discharge (Dart et al., 2009; Höllhumer et al., 2020) (Figs. 2 and 3).

A provisional diagnosis of AK can be made from the patient history, clinical features and confocal microscopy. *Acanthamoeba* cysts appear as hyperreflective, spherical and well-defined double-wall structures on confocal microscopy, while trophozoites are difficult to discriminate from leukocytes and keratocyte nuclei (Villani et al., 2014). Diagnosis should be confirmed via corneal scrape to identify the *Acanthamoeba* species. If clinical suspicion exists, the epithelial defect should be scraped using a sterile blade or needle under topical anesthesia (Ngo et al., 2020). The culture specimen should then be inoculated onto *Escherichia coli* plated over non-nutrient agar. As the clinical picture is often non-specific, cultures should be taken for bacterial, fungal and viral infection as well. Although culture on *E. coli* agar plates is the gold standard, polymerase chain reaction (PCR) testing can be performed as it is well established and has higher sensitivity; *E. coli* plates may also not be available in all centers (Ikeda et al., 2012; Lorenzo-Morales et al., 2015). The sample may also be placed on nutrient agar for transfer to *E. coli* plates in the laboratory (Dart et al., 2009). In the case of deep corneal involvement, a corneal biopsy maybe needed for diagnosis (Robaei et al., 2018) (Fig. 4).

Early diagnosis and aggressive medical therapy have improved the management of this often complicated infection. A combination of various antiacanthamoebal agents are utilized; there is no single drug that can eliminate both cystic and trophozoite forms. Due to the existence of cyst form which is highly resistant to therapy, a combination of agents is generally used. Topical

Fig. 3 Ring infiltrate in acanthamoeba.

Fig. 4 Confocal microscopy of acanthamoeba.

agents effective against acanthamoeba trophozoites and cysts are polyhexamethylene biguanide (PHMB) and chlorhexidine (Lorenzo-Morales et al., 2013, 2015). Both PHMB and chlorhexidine are effective against trophozoites with variable efficacy against cysts. Chlorhexidine is often used in combination with propamidine or hexamidine and has shown good results if the treatment is commenced early in the course of infection (Roberts and Henriquez, 2010). However, propamidine and hexamidine are not available in all countries. Topical anti-acanthamoeba drugs should be administered every hour after corneal scrape procedures for the first several days with the frequency then reduced depending on clinical response. Treatment is recommended for 6–12 months with close observation to prevent recurrent infection. Therapeutic penetrating keratoplasty is reserved as a measure of last resort in cases of impending corneal perforation. Robaei et al. suggests delaying corneal transplantations where possible, until the eye is no longer inflamed and after completion of antiacanthamoebal treatment (Robaei et al., 2015).

Should be considered when the infection spreads to the paracentral corneal stroma, as performing this procedure on a more localized infection may allow for the total removal of the organism (Cohen et al., 1987). Topical steroids may be needed to control inflammation but only after antiacanthamoebal therapy has been commenced (Carnt et al., 2016).

Acanthamoeba keratitis can be difficult to treat; it can lead to complications including scleritis and treatment toxicity. To prevent Acanthamoeba keratitis, clinicians should instruct patients on proper cleaning of contact lenses and remind patients to avoid wearing contact lenses while swimming or showering (Carnt and Stapleton, 2016).

Microsporidiosis

Microsporidiosis is an intestinal infection caused by *Microsporidia* species. The infection occurs worldwide and predominantly in patients with AIDS and causes chronic diarrhea, disseminated infection, and corneal disease. The source of *microsporidia* infection is still uncertain, but the genotype that infects humans have been identified in domestic, farm and wild animals (Mathis et al., 2005). Predisposing factors include poor sanitary conditions, close contact with domestic animal hosts (such as cats and birds), prolonged topical steroid use, immunocompromised, and contact lens use (Theng et al., 2001; Didier and Weiss, 2006). Once the parasite is

Fig. 5 Microsporidia keratitis caused by exposure to water well. Note the speckled fine opacities in the cornea. Image courtesy of Assistant Professor Tyler Hall from the University of Alabama Birmingham.

Fig. 6 Microsporidia keratitis. The images shows atypical punctate epithelial lesions. Image courtesy of Dr. Joshua Teichman from the University of Toronto.

inside the host, they inoculate the host cell with an infective sporoplasm. Intracellularly, the sporoplasm divides and multiplies, producing sporoblasts that mature into spores. The spores are then disseminated throughout the body or pass into the environment via respiratory aerosols, stool or urine. An inflammatory response occurs when the spores are released from the host cells (Didier and Weiss, 2006) (Figs. 5 and 6).

Clinical signs and symptoms vary depending on the parasite species and the immune status of the host. In immunocompetent patients, *microsporidia* can cause asymptomatic infection or self-limited watery diarrhea. In patients with AIDS, chronic diarrhea and malabsorption occur. Superficial keratoconjunctivitis can occur in both immunocompetent and immunocompromised patients. Both immunocompetent and immunocompromised patients typically experience redness, photophobia, pain, lacrimation and blurred vision, and present with signs of diffuse, raised, punctate, round epithelial lesions in the cornea, mimicking adenoviral keratoconjunctivitis (Loh et al., 2009; Das et al., 2012; Joseph et al., 2006). In immunocompromised patients, the presence of epithelial keratopathy, anterior or mid stromal infiltration, anterior uveitis and corneal necrosis and perforation have also been seen. Stromal keratitis has also been reported mostly in immunocompetent individuals (Joseph et al., 2006).

The gold standard for the identification of *microsporidia* is via TEM. In routine clinical practice, TEM is not feasible; corneal scrape or biopsy should be performed to identify the species of *microsporidia*. IFA and PCR can also be used to identify *microsporidia* species (Didier and Weiss, 2006).

The recommended treatment for microsporidiosis is albendazole as it is effective in controlling diarrhea. Stromal keratitis is generally refractory to medical therapy, and usually requires debridement of superficial corneal epithelium or penetrating keratoplasty. However, a case report has shown oral albendazole to be effective in treating stromal keratitis (Sangit et al., 2011). Microsporidial keratoconjunctivitis may be self-limited (Das et al., 2010) or require topical antibiotics such as fumagillin, fluoroquinolones and voriconazole (Loh et al., 2009).

Helminths

Helminths are large, free-living, multicellular worms that are generally visible to the naked eye in their adult stage (Table 2). In their adult form, helminths cannot multiply in humans. There are three main groups of helminths: flatworms (platyhelminthes), thorny-headed worms (acanthocephalins) and roundworms (nematodes).

Onchocerciasis

Onchocerciasis, also known as river blindness, is a disease caused by the parasitic worm *Onchocerca volvulus*. The infection is transmitted by bites from infected black Simulium fly, which breeds in rapidly flowing waters. It is an endemic in many areas of sub-Saharan Africa (World Health Organization, 2019c). Humans are the only host of *O. volvulus*, the larvae are transmitted through the bite of female black flies and develop into mature adult worms that form subcutaneous nodules. The adult female releases millions of microfilariae that can migrate throughout the body, particularly to the skin and eyes (Hoerauf et al., 2003).

Ocular manifestations of onchocerciasis are caused by the presence of dead parasites within the eye. The microfilariae infiltrate the eye through the bulbar conjunctiva at the limbus and invade the cornea, aqueous humor, iris, retina and choroid. Patients may present with punctate keratitis, sclerosing keratitis, anterior uveitis, iridocyclitis, glaucoma, chorioretinitis, corneal opacity and optic atrophy (Padhi et al., 2017; Hoerauf et al., 2003).

The diagnosis of onchocerciasis is via a combination of clinical signs and symptoms and a histopathological examination (i.e., skin, subcutaneous nodules, or sclerocorneal biopsy) (Udall, 2007). Microfilariae may be visible in the cornea and anterior chamber of the eye during slit-lamp examination. PCR can also detect their DNA and is more sensitive than standard techniques (i.e., skin snips or biopsies) but is typically only used in research settings (Boatin et al., 2002).

The recommended treatment is ivermectin; it reduces the production of microfilariae in the eye. Ivermectin does not kill the adult female worms, instead, in cumulative doses, it decreases their fertility. A single dose of 150 µg/kg, repeated for 6–12 months interval is recommended (World Health Organization, 2019c). Doxycycline has also been used to decrease microfilaria load and corticosteroids to reduce inflammation.

Loiasis

Loiasis, also known as the African eye worm, is caused by the *Loa loa* worm. It only occurs in Africa, primarily in rainforest areas of Central and West Africa (Barnett, 2007). Individuals living in the rainforest in Central and West Africa and travelers visiting those areas are at high risk of infection (Centers for Disease Control and Prevention, 2015). Transmission of the disease is caused by bites from tabanid flies (also known as deer fly or horse fly). Immigrants from or travelers to an endemic area are at risk of contracting the infection (Barnett, 2007).

Table 2 Summary of helminths parasitic infections with ocular involvement.

Disease (causative agent)	Mode of transmission	Geographical distribution	Ocular pathology	Treatment
Onchocerciasis (<i>Onchocerca volvulus</i>)	Bites by female black flies	Sub-Saharan Africa	Punctate keratitis, sclerosing keratitis, anterior uveitis, iridocyclitis, glaucoma, chorioretinitis, corneal opacity and optic atrophy	Ivermectin, doxycycline, corticosteroids
Loiasis (<i>Loa loa</i>)	Bites by tabanid flies	Central and West Africa	Worm under bulbar conjunctiva, chemosis, pruritus, keratitis, iritis, retinal hemorrhages	Removal of worm, DEC
Toxocariasis (<i>Toxocara canis</i> , <i>Toxocara cati</i>)	Ingestion of contaminated food or water of stool from infected animal, ingestion of undercooked infected transfer hots (e.g., rabbits)	Worldwide	Posterior pole granuloma, peripheral granuloma, nematode endophthalmitis	Albendazole, corticosteroids
Cysticercosis (<i>Cysticercus cellulosae</i>)	Ingestion of water or food contaminated with eggs or tapeworms, ingestion of raw or undercooked infected pork	Developing countries of Africa, Asia, Latin America	Orbital or intraocular cyst	Albendazole, corticosteroids, surgical removal of cyst

Key: spp., species; DEC, diethylcarbamazine.

Transmission occurs when humans are bitten by the fly which passes microfilariae to the human, where they develop into mature adult worms (Centers for Disease Control and Prevention, 2015). The adult worms migrate through cutaneous and deep connective tissue, producing microfilariae. The presence of microfilaria or adult worms can cause ocular diseases. A migrating worm in the periorbital area may cause intense itching, swelling and a moving foreign body sensation, while a dead worm can incite inflammation, leading to conjunctival congestion, chemosis, pruritus, keratitis, iritis, retinal hemorrhages and even blindness (Padhi et al., 2017; Klion et al., 1991; Bowler et al., 2011).

Loiasis is usually diagnosed by the detection of circulating microfilariae. In cases of conjunctival involvement, removal of an adult worm confirms the diagnosis. Serology can be performed to detect microfilariae in the blood with samples taken between 10 am and 2 pm when microfilariae levels are the highest (Centers for Disease Control and Prevention, 2015). Treatment for the infection requires manual removal of adult worms present in the conjunctiva and the use of oral diethylcarbamazine (DEC). Clinicians should monitor patients with severe infection closely, as patients prescribed DEC are at risk of potentially fatal encephalopathy, due to the release of antigens from dying microfilariae (Padhi et al., 2017).

Toxocariasis

Toxocariasis is a zoonotic disease caused by the larva of *Toxocara canis* (dogs) or *T. cati* (cats). It is distributed worldwide and is the most prevalent helminthic infection in tropical, developing countries (Mattos et al., 2016). Animals of canine and feline species act as definite host, humans are the accidental host. Geophagia and exposure to and/or ownership of puppies and kittens have been identified as significant risk factors (Nathwani et al., 1992). Humans may accidentally ingest eggs in food or water contaminated by stool from infected animals or from ingesting of undercooked infected transfer hosts (e.g., rabbits).

In the definite animal host (i.e., dogs and cats), the larvae mature into adult forms and liberate eggs in their feces. In humans, the parasite faces a dead end, that is the larvae doesn't mature into the adult form, though can remain alive in the human host for many months. In the human host, the larvae hatched in the intestines, penetrate the bowel walls and migrate through to the liver, lungs, eyes and other tissues (Despommier, 2003). Patients usually present with systemic symptoms of fever, cough, hepatomegaly and rash (Padhi et al., 2017). In certain cases, ocular toxocariasis can occur. This is caused by a single larva entering the ocular circulation and typically affects older children. It is usually unilateral with little to no evidence of systemic manifestations. The main ocular findings include posterior pole granuloma, peripheral granuloma, and nematode endophthalmitis (Ahn et al., 2014a) (Fig. 7).

Diagnosis of ocular toxocariasis is presumptive and typically based on patient history, clinical observation and serologic findings. The standard tests for diagnosing toxocariasis in humans is the detection of serum IgG using ELISA based on the *Toxocara* larval antigen (Ahn et al., 2014a). A biopsy to obtain the infected tissue can be performed but is risky and difficult in eyes with ocular toxocariasis, and thus rarely performed.

The infection is usually self-limiting in asymptomatic patients and those with mild symptoms. For patients with moderate to severe infection, systemic albendazole is the recommended drug of choice (Ahn et al., 2014a; Padhi et al., 2017). For ocular toxocariasis, currently, no optimal treatment regime has been established. However, systemic and periocular steroids are usually administered to control inflammation (Ahn et al., 2014b). For structural complications in the retina (e.g., retinal detachment, epiretinal membrane, and persistent vitreous opacity) vitreoretinal surgery may be performed (Ahn et al., 2014a).

Cysticercosis

Cysticercosis is a systemic illness caused by *Cysticercus cellulosae* larvae of the adult tapeworm *Taenia solium* and *Taenia saginata* (Dhiman et al., 2017). It can affect the skin, skeletal muscles, heart, eye and central nervous system. It is a common cause of ocular

inflammation in developing countries of Africa, Asia and Latin America (World Health Organization, 2019a). Cysticercosis is caused by ingestion of water or food contaminated with tapeworms or eggs, or ingestion of raw or undercooked infected pork. In ocular cysticercosis, the egg matures into larvae and penetrates the intestinal mucosa and spreads hematogenously into the eye (Carpio et al., 2013). Ocular cysticercosis typically affects the younger age group, occurring most commonly between the ages of 10 and 20 years (Pushker et al., 2004; Dhiman et al., 2017).

The cysticercus larvae can affect almost any part of the eye such as the anterior orbit, subconjunctival space, posterior orbit and eyelid. Depending on the location of the cyst, patients may present with the following: decreased visual acuity, pupillary blocking leading to glaucoma, conjunctiva or scleral redness, proptosis, lid swelling, exudative or rhegmatogenous retinal detachment or optic disc edema (Dhiman et al., 2017).

Diagnosis is based on clinical features, serological and radiological examination. Depending on the location of the cysts, the use of B-scan ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI) are most helpful in providing a definitive diagnosis. Serologic tests such as ELISA can identify antibody against excretory-secretory antigens (i.e., IgG) but have a low sensitivity in diagnosing cysticercosis (Dhiman et al., 2017; Diwan et al., 1982).

The treatment for ocular cysticercosis is oral albendazole (Sihota and Honavar, 1994) and may lead to increased inflammation around the lesions requiring the use of corticosteroids. Surgery may also be required for isolated ocular lesions to prevent vision loss.

Ectoparasites

These are parasites that live on the external surface of the host and depend on blood meals from a human host for their survival, for example, fleas and lice (Table 3).

Ophthalmomyiasis

Ophthalmomyiasis is the result of an invasion of dead or living vertebrate animal tissue by fly larvae into the eye. Genera commonly associated with human myiasis include *Dermatobia*, *Gasterophilus*, *Oestra*, *Cordylobia*, *Chrysomya*, *Wohlfahrtia*, *Cochliomyia*, and *Hypoderma* (Francesconi and Lupi, 2012). It is common in rural farming regions. Myiasis usually follows a seasonal pattern, in accordance with the insect's life cycle, i.e., most cases occur during spring and summer in temperate climates (e.g., Europe, Northern America and Northern Africa) (Padhi et al., 2017).

Many flies do not lay their eggs on humans but on other insects, animals or objects that may come into contact with skin. Female flies retain their eggs within their body until they hatch. Once they hatch the larvae can burrow into the skin and develop and grow into mature larvae. Although some flies are attracted to open wounds some species infest unbroken skin (Francesconi and Lupi, 2012). When they occur in the eye, larval infections are usually restricted to the conjunctiva and cornea. There are three categories of ophthalmomyiasis: ophthalmomyiasis externa, ophthalmomyiasis interna and orbital myiasis.

Symptoms vary based on the biology of the larvae, the location in the eye, and route of penetration. Ophthalmomyiasis externa refers to the superficial infection of ocular tissue, i.e., conjunctival involvement. Patients typically experience itching, pain, conjunctival hyperemia, lid edema, lacrimation and foreign body sensation (Anane and Hssine, 2010). These signs may mimic conjunctivitis. This type of ocular myiasis is typically mild, self-limited and benign.

Ophthalmomyiasis interna is an infection involving the anterior or posterior segment of the eye. The fly larva may be seen in the anterior segment, vitreous and/or subretinal space (Jakobs et al., 1997). This type of infection is not common and clinically appears as anterior uveitis, sometimes accompanied by posterior segment inflammation. Patients may present with iritis, retinal detachment or subretinal tracks. Symptoms usually include red eye, vision loss, floaters, pain and scotomas (Francesconi and Lupi, 2012).

Table 3 Summary of ectoparasites parasitic infections with ocular involvement.

Disease (causative agent)	Mode of transmission	Geographical distribution	Ocular pathology	Treatment
Myiasis (<i>Dermatobia</i> , <i>Gasterophilus</i> , <i>Oestra</i> , <i>Cordylobia</i> , <i>Chrysomya</i> , <i>Wohlfahrtia</i> , <i>Cochliomyia</i> , and <i>Hypoderma</i>)	Insects, animals or objects that may come into contact with skin	Europe, Northern America and Northern Africa in rural farming regions	Ophthalmomyiasis externa: itching, pain, conjunctival hyperemia, lid edema, FBS ophthalmomyiasis interna: iritis, retinal detachment, subretinal tracks orbital myiasis: proptosis, congestion, chemosis and discharge	Removal of worms from accessible location, corticosteroids, exenteration
Lice (<i>Pediculus pubis</i>)	Intimate "skin to skin" contact or transmitted by fomites	Worldwide	Small erythematous papules, crusting of the eyelid margin	Manual removal with forceps of visible lice and eggs, petrolatum, physostigmine ointment, oral ivermectin

Key: FBS, foreign body sensation.

Orbital myiasis is a severe infestation characterized by the intraocular invasion of maggots from the eyelid myiasis. Eyelid tumors are the most common predisposing factor for this type of ophthalmomyiasis (Çaça et al., 2006; Cavuşoglu et al., 2009; Jain et al., 2007). Patients typically present with proptosis, congestion, chemosis and discharge (Padhi et al., 2017).

Diagnosis is made via patient history and physical examination. Establishing a history of a patient's recent close contact with farm animals (specifically sheep or goats) in a rural area may aid diagnosis (Nimir et al., 2012). Additionally, a slit lamp exam may reveal small translucent larvae up to 5 mm in length on the conjunctiva. Because the larvae are photophobic, it is prudent to examine the eye and discharge under moderate slit lamp illumination and high magnification (Francesconi and Lupi, 2012). Ocular myiasis should be considered in cases of unilateral foreign body sensation.

The mainstay of treatment is the removal of the larvae, often at the slit lamp, with topical analgesics and antibiotics. Removal of the larvae may be difficult due to their strong attachment to tissue. Corticosteroids may be used to treat inflammation. Symptoms tend to resolve immediately after removal of the larvae. In severe cases, exenteration may be required to prevent the intracranial extension of tissue destruction (Francesconi and Lupi, 2012).

Lice

Lice are wingless, blood-sucking insects that infest the head (*Pediculus humanus* var. *capitis*), body (*P. humanus* var. *corporis*) or pubis (*P. pubis*). Involvement of the eyelashes and eyelids is caused by *P. pubis* (Rundle and Hughes, 1993). The infestation occurs worldwide and is associated with poor hygiene, overcrowding and is more common in the sexually active age group of 15–45 years (Kiran et al., 2012). Transmission occurs from close contact, often intimate “skin to skin” contact, or is transmitted by fomites (e.g., towels, bedding, clothing) (Rundle and Hughes, 1993).

Depending on the species, eggs or nits are laid and glued to body hairs or clothing fibers. This results in nymphs emerging to feed on the host, leading to symptoms of pruritus. Small erythematous papules with evidence of excoriation and crusting of the eyelid margin may also be seen (Karabela et al., 2015).

Diagnosis can be confirmed via slit lamp examination, as the lice anchors to the eyelashes or eyebrows. Manual removal with forceps of visible lice and eggs is the standard treatment but can be tedious and unsuccessful due to the firm adherence of eggs to the eyelash. Application of petrolatum, physostigmine ointment, and/or oral ivermectin can increase the effectiveness of treatment (Karabela et al., 2015).

Introduction

The human ear is exposed to the external environment and the internal environment of the upper airway (Fig. 1). Thus it is susceptible to both exogenous and endogenous acquired bacterial infections. Those infections that occur within the ear canal are otitis externa while those that occur in the space behind the tympanic membrane are otitis media (OM).

OM is among the most common human infections. OM can occur at any age, but OM is most commonly seen in the first 3 years of life. OM is the most frequent cause for sick-baby visits to the pediatrician, and the reason for most antibiotic prescriptions (Gonzales et al., 2001).

OM is an inflammatory disease of the middle ear of which there are various forms. This includes acute otitis media (AOM) (Fig. 2), otitis media with effusion (OME), and chronic supportive otitis media (CSOM). Each of these forms of OM are sometimes described as distinct diseases. There is overlap among the different forms, and it is sometimes not easy to distinguish between the progressions of the disease. However, AOM is described as acute suppurative OM with pus in the middle ear and rapid onset of fever and irritability or ear pain in young children. OME presents as middle ear fluid without the signs of bacterial infection. OME can occur in children after the AOM subsides. CSOM involves a perforation in the tympanic membrane and a persistent drainage for weeks from the middle ear. Additionally, recurrent AOM involves multiple episodes of AOM over a short period of time.

In contrast to OM, infections that result in inflammation of the ear canal are defined as otitis externa. Fig. 3 is from an animal model showing inflammation as a result of bacterial infection. Acute otitis externa (AOE) is commonly referred to as swimmers ear. Cerumen, or ear wax, is an important component in the defense of the external ear canal. Too much or too little cerumen can predispose the external ear canal to infection.

Pathology, epidemiology, and pathogenesis of bacterial OM

The bacteria that cause OM colonize the nasopharynx. They can then transition to the middle ear via the Eustachian tube. The Eustachian tube functions to maintain air pressure within the middle ear and clear mucus from the middle ear to the nasopharynx. To accomplish this, the tube opens and closes periodically. This can provide a pathway for bacteria to reach the middle ear. Additionally, in young children the angle of the Eustachian tube between the middle ear and the nasopharynx is relatively flat becoming more acute as the child develops. This lack of angle increases access to the middle ear from the nasopharynx.

There are a number of factors that can contribute to the development of OM. Probably younger age is the chief risk factor. Attendance at daycare can also predispose young children to the development of OM. Daycares provide a stressful environment of close contact and sharing of objects. This can increase the rate of colonization in the nasopharynx by those bacteria that cause OM. Household smoking can impact the overall health of young children and increase the occurrence of OM. OM is more frequently seen in children who are formula fed from birth. In contrast breast feeding can be protective.

As much as 70% of AOM is caused by bacteria. This is often preceded by viral infections of the upper respiratory tract. The viral infection can alter the responses in the nasopharynx leading to an over production of proinflammatory cytokines. Additionally, there may be cellular damage during the viral infection. These and other factors can increase the potential for a bacterial infection of the middle ear.

The leading bacterial causes of OM include *Streptococcus pneumoniae* (pneumococcus), nontypeable *Haemophilus influenza* (NTHi), and *Moraxella catarrhalis*. Infections with these bacteria can occur singularly or in combination. Prior to the introduction of the pneumococcal conjugate vaccine (PCV), the pneumococcus was considered the leading cause of OM, and the capsule polysaccharide was considered the major virulence factor for the organism. This formed the basis for the development of the PCV.

Most cases of OM are treated empirically, and the etiological agent is not determined. While the PCV has had a dramatic effect on the pneumococcal invasive disease, the incidence of OM has not decreased. This is due in part to the other otopathogens, NTHi and *M. catarrhalis*. However, a consequence of the PCV has been the selective pressure on the pneumococcus. This has resulted in serotype replacement by pneumococcal serotypes that are not covered by the vaccine. Additionally, there has been the emergence of nonencapsulated *S. pneumoniae* (NESp) as a cause of OM (Bradshaw and McDaniel, 2019). It is not clear if the NESp lineage

Fig. 1 A topographical representation of the human ear.

Fig. 2 Acute otitis media. A view through an otoscope of (A) a normal ear and (B) an infected ear with fluid and bubbles behind the tympanic membrane. Note that these images are from an animal model of infection.

Fig. 3 Otitis externa. Guinea pigs were infected in the OEC with *Pseudomonas aeruginosa*. The ear canals were harvested, sectioned, and stained with hematoxylin and eosin. The control is from a sham infected animal. It shows intact squamous epithelial cells with underlying tissue. The section from the infected animal shows desquamation of the epithelium, inflammation, and infiltration of neutrophils.

represents variants that arose because of the selective pressure of the PCV. Alternatively, NESp may have been in circulation and are now being detected through screening for disease isolates following the introduction of the vaccine. It is clearly known that NESp do play a role in human disease.

NESp have been primarily associated with upper respiratory diseases such as OM, sinusitis, adenoiditis, and pneumonia (Keller et al., 2016b). These NESp naturally lack a polysaccharide capsule but are able to compensate, survive within the host, and cause infection. NESp form biofilms and are efficient in taking up DNA from other strains. NESp can be resistant to multiple antibiotics. Thus, NESp may serve as a resistance reservoir for encapsulated strains and possibly other bacterial strains.

The mechanism that allow NESp to cause disease in the absence of pneumococcal capsular polysaccharide is not fully understood. At least three virulence factors have been identified that are encoded in place of the genes required for capsule production. These are PspK, AliC, and AliD. PspK has been demonstrated to increase adherence to epithelial cells and is required for full virulence in OM in the chinchilla model. AliC and AliD are permeases that transport small peptides. The peptides act as environmental signals that cause a change in the bacterial surface depending on its location within the host. These changes have been shown to lead to increased complement resistance when AliC and AliD are expressed. This has implications for OM and other NESp infections.

Encapsulated pneumococci have additional factors that allow them to cause OM. Pneumolysin, a pore forming toxin, and pneumococcal surface proteins are involved in pneumococcal virulence in the chinchilla model of OM (Keller et al., 2016a). Additionally, DNA methylation can alter pneumococcal gene expression and plays a role in virulence.

NTHi has increased as a causative agent of OM. There are a number of surface exposed virulence factors that are being studied. These include adhesins that bind to lectins within the airway. Also, surface proteins have been shown to bind to human extracellular matrix which can contribute to persistence in the middle ear.

Like most airway pathogens, NTHi exist in biofilms during disease. DNA plays a role in the formation of biofilm by NTHi. These structures are important both in colonization and OM. The formation of biofilm during infection reduces the chances of clearance of the NTHi. Also, the regulation of gene expression within the host environment contributes to the ability of NTHi to cause disease. For example, the lack of iron in the middle ear leads to increased expression of iron acquisition genes by NTHi.

M. catarrhalis is a cause of OM in children. Like NTHi, adhesins are important in the attachment of *M. catarrhalis* to human epithelial cells and extracellular matrix. *M. catarrhalis* has a family of trimeric autotransporter adhesins (TAAs) that act as multi-functional virulence factors. Proteins among this family are thought to play a role in blocking complement activation which is the first line of defense against many pathogens.

Biofilm formation by *M. catarrhalis* is also important for persistence in the middle ear. Extracellular DNA is an important part of the scaffolding of the biofilm. Regulation of a nuclease that can degrade extracellular DNA could allow for aggregation of *M. catarrhalis* early in infection and then release of the bacteria later in infection which could lead to spread.

Co-infection of the middle ear with more than one bacterial species at a time can contribute to disease progression. *M. catarrhalis* produces a beta-lactamase that can inactivate penicillin. Thus an OM co-infection of *M. catarrhalis* and *S. pneumoniae* could result in protection of the pneumococcus from penicillin therapy.

Complications

AOM often resolves spontaneously without any complications. In some cases there can be perforation of the tympanic membrane. Perforations can be acute or chronic. This can progress to CSOM. Also, recurrent episodes of OM can lead to scarring of the tympanic membrane which results in hearing loss. In rare cases there can be intracranial complications such as meningitis. Morbidity can be significant despite the use of systemic antibiotics for treatment of OM. In fact, the systemic antibiotics can cause problems by altering the normal bacterial flora outside of the targeted area.

Otitis externa

Acute otitis externa (AOE), commonly known as swimmer's ear, can occur in up to 10% of the population. It presents as a generalized inflammation of the external auditory canal (EAC) and is almost exclusively a bacterial infection. Infection can occur in any age group but is more frequently seen in 2–18 year olds with a peak incidence in 5–14 year olds. Also, cases have been linked to the use of aural irrigation instruments contaminated with bacteria. When infections do occur, bacteria cause >90% of AOE with *Pseudomonas aeruginosa* being the most common causative isolate. AOE results in a substantial personal burden due to increased medication use and an inability to carry out daily activities.

The EAC is a tube running from the outer ear to the tympanic membrane and is covered by a thin layer of skin. Cerumen is thought to be an important component in the defense of the EAC against infection. Cerumen is acidic and contains lysozyme which may impede bacterial growth to help protect the EAC. It is likely that changes in the EAC environment can predispose the EAC to infection.

P. aeruginosa is an opportunistic pathogen that causes a range of infections, is present in many different environments, and is often part of the skin flora of humans. It is likely that the external ear canal is frequently exposed to *P. aeruginosa*. However, the mechanisms by which *P. aeruginosa* can establish an infection in the ear canal and persist are largely unknown. The pathogenesis of

P. aeruginosa is complex. There is variability in *P. aeruginosa* isolates compared to those that cause AOE. This suggests that there may be specific pseudomonas virulence factors that are required for infection of the EAC. Identification of these virulence factors, and their role in AOE could result in better interventions and possible prevention of infection.

There have been a number of studies that have identified risk factors associated with AOE. Probably the most significant risk factor is swimming in fresh water. Previous episodes of AOE can be a risk factor as well as the regular use of devices that block the ear canal. This includes hearing aids, ear plugs, and earphones. These devices can cause trauma and irritation to the skin in the ear canal predisposing to infection. Hot humid weather can be a contributing factor. Also, excessive cleaning of the ear canal can remove ear wax which can potentially lead to infection. Comorbidities such as diabetes and malnutrition can predispose to infection of the EAC.

The overall impact of AOE is not known, but it has been estimated that millions of prescriptions are processed in the United States each year as a result of this infection. This does not take into account physician visits, loss of productive time, and personal discomfort. Often, AOE is thought to be a self-limiting and self-resolving disease. Current clinical guidelines recommend topical treatment for AOE without complications. However, many patients with uncomplicated AOE receive systemic antibiotics. Clearly there is a need to better understand this medically important infectious disease.

Complications resulting from AOE are usually uncommon. Some individuals will have repeated episodes of AOE or persistent inflammation of the EAC for more than 3 months. This condition is known as chronic otitis externa. Other complications may include abscesses in the EAC which are painful pus-filled growths persisting after the infection. Stenosis, a narrowing of the ear canal, can result from a build-up of thick dry skin. This is more likely to occur as a result of chronic otitis externa. Cellulitis may occur as a result of AOE. The bacteria may penetrate deeper layers of the EAC skin as a result of damage during AOE. This would require more extensive treatment to resolve. Malignant otitis externa is a very rare but serious complication of AOE that occurs mainly in immunocompromised adults. The infection spreads to the bone surrounding the EAC.

Summary

Bacterial ear infections can occur in anyone at any age. OM is an infection of the middle ear. This infection occurs primarily in young children and remains the main reason for sick baby visits to the pediatrician. This is true even with available vaccines. The economic burden is not just that of the doctor visit, but also, there is the lost work time for parents that have to tend to the child. AOE has different concerns because it tends to occur in people of a productive age and can impact their ability to work. The range of infections involving the ear can be from very mild to severe with significant complications. There needs to be a continued focus on understanding host-pathogen interactions in the diseases of the ear.

Acute middle ear infection, acute otitis media (AOM) is one of the most common infectious diseases in children; about two thirds of children have at least one AOM episode by the age of 2 years (Nokso-Koivisto et al., 2015; Schilder et al., 2016). In adults, acute otitis media occurs rarely, but the role of viruses in the pathogenesis of acute middle ear infection in adults do not differ from children. The role of viruses in the pathogenesis of middle ear infection with effusion is uncertain and studies very limited. Thus, this chapter will focus on the role of respiratory viruses in acute middle ear infections.

AOM is considered to be a bacterial complication of viral upper respiratory tract infection (URI). However, viruses alone can cause AOM. The high incidence of AOM results from the high burden of viral URIs. About 35% of URI episodes are complicated by AOM, occurring mainly within the first week of URI onset.

The association between respiratory viruses and AOM

Infections caused by respiratory viruses are the most common diseases in children around the world. Viral upper respiratory infection is usually mild and self-limiting, but sometimes complicated by bacterial infections such as AOM. Multiple respiratory viruses are of hundreds of different serotypes which can cause the common cold or respiratory infection leading to AOM.

The association of viral infections and development of AOM has been shown in several different studies (Chonmaitree et al., 2015, 2016; Nokso-Koivisto et al., 2015). An epidemiologic association between the outbreaks of viral infections and a simultaneous increase in AOM incidence has been demonstrated e.g., in a 14-year longitudinal study in which concurrent or previous respiratory infection was associated with one-fourth of AOM episodes (Henderson et al., 1982).

Viral respiratory infections have been shown to alter middle ear pressure, which in turn can cause accumulation of mucus and pathogenic agents in the middle ear. Studies of experimental and natural viral infections in children and adults have shown that up to two thirds of patients develop negative middle ear pressure during upper respiratory infection and may develop middle ear effusion negative for bacteria.

Although AOM is often bacterial or viral-bacterial co-infection, there is evidence that respiratory virus alone can cause AOM. Experimental studies in adults and in chinchillas have shown that induced virus infection can lead to the development of AOM. It has been reported that children infected with respiratory syncytial virus (RSV) have an increased risk of AOM even without colonized bacteria (Ruohola et al., 2013). In addition, respiratory viruses have been detected in majority of nasopharyngeal specimens and up to 70% middle ear fluid samples in children with AOM, and viruses or viral nucleic acids have been detected from middle ear fluid of children with AOM even in absence of bacteria. Table 1 presents selected studies of viruses detected from middle ear fluids at the time of AOM including the very first study from the year 1955 (Yoshie (1955)). The table also demonstrate the development of viral detection methods from culture to antigen detection and polymerase chain reaction (PCR), and the difficulties in detecting viruses. The wide variety in the proportion of virus positivity in middle ear fluids is mainly due to difficulties in isolating viruses and different sensitivities of the tests, although seasonal variation of the viral infections may have a role. In addition, as all respiratory viruses are not detectable with a single test, combining different detection methods (culture, antigen detection, PCR, serology) has been necessary to cover most of the important causative viruses. For example in a study (Ruohola et al., 2006) using multiple detection methods, the proportion of virus positive middle ear fluids was the highest. Lately PCR has been the main detection method, as it is usually more sensitive than viral culture or antigen detection methods and has been developed for many respiratory viruses.

Evidence of an association between viruses and AOM has also been based on virus-specific intervention studies. AOMs occurring during influenza outbreaks can be prevented by immunizing children with influenza virus vaccine or by giving specific antiviral treatment at the time of influenza virus infection (Block et al., 2011; Heikkinen et al., 2013; Heinonen et al., 2010). In addition, high doses of RSV-enriched immunoglobulin have been reported to prevent development of AOM in high-risk children (Simoes et al., 1996).

Table 1 Selected data from studies of viruses detected from middle ear fluid (MEF) in children with acute otitis media (AOM).

Study	No. of children with AOM	No. of MEF	Virus detection method ^a	Proportion of virus-positive MEF (%)

Pathogenesis of virus-induced AOM

AOM usually occurs concurrently or just after upper respiratory tract infection. More than 90% of children with AOM have previous or concurrent respiratory infection. The three most common bacterial otopathogens: *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*, and *Moraxella catarrhalis* can colonize the infant's nasopharynx from early age. However, usually these pathogens do not infect the respiratory tract or cause symptoms until viral infection, which causes nasopharyngitis and changes of the nasopharyngeal milieu. The coexistence of bacterial otopathogens and the interactions between bacteria and respiratory viruses effect on the respiratory infection course and eventually on AOM outcome. To current knowledge, viral infection is needed to start this cascade of development of AOM.

The role of viruses in the pathogenesis of AOM has been studied in experimental animal models, in vitro studies, studies of adult volunteers infected with respiratory viruses, and studies of children with URI (Nokso-Koivisto et al., 2015; Schilder et al., 2016; Thornton et al., 2020). At start respiratory viruses cause inflammation of the nasopharynx and the Eustachian tube, generating host immune and inflammatory responses, including the generation of cytokines, chemokines and inflammatory mediators. Viral infection also increases nasopharyngeal colonization and adherence of bacteria to epithelial cells, and diminish the normal ciliary clearance of the nasopharyngeal and tympanomastoid mucosal cells. This leads to Eustachian tube dysfunction and negative pressure in the middle ear and entrance of colonized bacteria and respiratory viruses from the nasopharynx into the middle ear cavity. Thus the middle ear mucosa is infected, leading to middle ear fluid accumulation and development of signs and symptoms of AOM (Fig. 1).

**Fig. 1** Pathogenesis of virus induced acute otitis media.

Viruses as AOM pathogens

The most common respiratory viruses in humans are adenoviruses, human bocaviruses, coronaviruses, enteroviruses, influenza viruses, human metapneumoviruses, respiratory syncytial virus (RSV) and rhinoviruses. Any respiratory virus that can cause upper respiratory infection can initiate development of AOM as described earlier. However, it has been suggested that certain viruses are more likely to cause AOM than others, to be more “ototropic.” Among the common respiratory viruses, RSV has long been identified as AOM-associated virus. Because of the high prevalence of rhinovirus-URI in general, even without an increased rate of AOM development after URI, rhinoviruses are also considered common AOM-associated viruses. Respiratory virus testing of more than 96,000 specimens from children over 8 years showed that detection of RSV, human metapneumovirus and influenza was temporally associated with increased diagnoses of AOM (Stockmann et al., 2013).

With the widespread use of molecular diagnostics, respiratory viruses have been detected in up to 50% of asymptomatic young children. However, it has been shown that AOM development following URI requires an inflammation severe enough to initiate the expression of URI symptoms. It has been shown that AOM does not occur following asymptomatic viral infections, but symptomatic URI can lead to AOM in 27% of children in the first year of life (Chonmaitree et al., 2015).

Role of specific virus types in AOM

RSVs are some of the most important respiratory viruses to cause infections in children. RSV infections are present in all age groups, but they predominate in children and especially in infants. Up to 70% of infants have been reported to be infected with RSV during the first year of life, and the rest are infected by the age of 2 years. RSVs are the leading cause of bronchiolitis and acute wheezing in young children. Typically, RSV epidemics occur during the winter months, sometimes starting in the late fall and continuing until early spring. It has been suggested that RSV infection often leads to AOM, and AOM can develop in almost two thirds of the children with RSV infection.

Human metapneumovirus is a virus related to RSV and the clinical symptoms caused by metapneumovirus are similar to those due to RSV. This virus is an important cause of lower respiratory infections and wheezing in children, but it does not seem to be prone to cause AOM. Metapneumovirus infections occur mainly between winter and early spring.

Human rhinoviruses are important in AOM development since rhinoviruses are the predominant cause of the common cold all over the world and in all age groups. Many follow-up studies have shown that rhinoviruses are the most commonly detected viruses at the time of URI and often associated with AOM in children. Rhinovirus infections typically occur in the early fall and in the spring.

Enteroviruses, which belong to the same virus family Picornaviridae as rhinoviruses, are very common worldwide, and most primary infections occur in childhood. Often enteroviruses have been thought to cause mild diseases with characteristic signs (e.g., hand, foot, and mouth disease and herpangina) or more severe diseases such as meningitis. However, it has been shown that enteroviruses are also a common cause of URI and AOM in children.

There are three types of influenza viruses in humans, types A, B and C. However, most data about influenza viruses are for types A and B because, due to detection difficulties, influenza C viruses have not been included in the studies. Influenza type A and B cause infections that can range from asymptomatic infections and common colds to serious illnesses with systemic complications, such as pneumonia. Influenza A and B infections typically occur in a seasonal pattern and in winter epidemics, which have variable intensities. Especially influenza vaccine and treatment studies have shown that prevention of influenza infections will reduce the incidence of AOM and influenza viruses are important cause of AOM.

Human bocavirus has been associated with respiratory infections and has been suggested to be ototropic (Nokso-Koivisto et al., 2015). The possible prolonged presence of bocaviruses in the nasopharynx have made the causality of virus detections to the disease difficult to interpret. However, population-based studies with control groups have shown associations between bocavirus detection (high viral load) or seropositivity and symptoms of URI and the diagnosis of AOM.

It seems that human coronavirus infections are not very common cause of respiratory infections in young children, whereas later in life, clinical and subclinical infections occur more often. Pandemic coronavirus COVID-19 does not seem to be prone to cause AOM.

Viral-bacterial interactions in AOM

The most important risk factors for AOM development are the colonized bacterial otopathogens in the nasopharynx, the presence of respiratory viruses and their complex interactions (Marom et al., 2012). Respiratory viruses pave the way for otopathogens. In children with URI, those who are colonized with otopathogens are more likely to have concomitant AOM than those who are not. AOM risk seems to differ by the specific viruses and bacteria involved, e.g., detection of *M. catarrhalis* together with RSV or rhinovirus from the nasopharynx increases the risk of AOM (Chonmaitree et al., 2016). Studies have also aimed to determine the level of bacterial and viral loads that are sufficient enough to cause AOM, but the results so far have been conflicting.

The presence of respiratory viruses in the nasopharynx is not enough for the development of AOM; viral replication and the symptoms caused by the viral infection are also necessary. In animal studies e.g., infection with adenovirus increased the proportion of *S. pneumoniae* AOM compared to infections with bacteria alone. However, infection with nonreplicating adenovirus did not

increase the incidence of bacterial AOM (Murrah et al., 2015). Nasopharyngeal microbiota studies have also shown that the more URIs the children have in the first months of life, the more otopathogens there are in the nasopharynx. In addition, the presence of otopathogens is associated with symptomatic viral infection (Chonmaitree et al., 2017).

Viruses in AOM -Clinical implications

The knowledge on the importance of viruses in AOM has clinical implications, specifically on the treatment and prevention. The overall goal would be prevention of viral URI and to reduce or prevent nasopharyngeal colonization of bacterial otopathogens. In addition to reducing environmental risk factors for URI and AOM, the use of bacterial and viral vaccines would make a significant impact.

Prevention of viral URI is complicated because of the variety of numerous respiratory virus types that are associated with URI. So far, the only effective and widely used respiratory virus vaccine in influenza vaccine. It has been shown that trivalent, inactivated influenza vaccines and live-attenuated influenza vaccines effectively prevent influenza and influenza-associated AOMs (Block et al., 2011; Heikkinen et al., 2013). Surprisingly, intranasal live-attenuated influenza vaccines can also decrease the overall rate of AOM during influenza season despite the cause of AOM (Heikkinen et al., 2013). In addition, there has been studies on prevention of AOM by early treatment of influenza in children; treatment with oral oseltamivir significantly reduced new AOM in young children with laboratory-confirmed influenza infection (Heinonen et al., 2010).

Unfortunately, no other vaccines for common respiratory viruses are available. Any future progress towards vaccination against common respiratory viruses in addition to bacteria would have an impact on reducing the burden of AOM (Alderson et al., 2020).

Respiratory viruses in otitis media with effusion

It has been suggested that respiratory viruses, along with bacteria, also have a role in otitis media with effusion (OME) by being a latent infections in the middle ear or by presenting a pathogen reservoir in the nasopharynx and adenoid. Respiratory viruses have been detected from the adenoid tissue and middle ear secretion or middle ear washes of children with OME. However, respiratory viruses have been detected in similar proportions of the children without OME. The role of the viruses in the pathogenesis is uncertain and studies limited. Respiratory viruses do not seem to have major role in OME.

Otomycosis in history

Andral and Gavarret (1843) were the first to describe a case of otomycosis in 1843; a year later, Mayer reported a disease of the external auditory canal caused by a fungus, documenting the presence of a “mycotic parasite in the push of a draining ear” (Mayer, 1844). Highet wrote: “*Otomycosis, or the growth of fungus in the external auditory meatus, is apparently a rare disease in temperate climates if one may judge from the scanty literature on the subject. During eight years’ work in Singapore and Bangkok, however, my experience has been that it is quite a common—if not the most common—disease affecting the external auditory meatus which one meets with in the tropics*” (Highet, 1900).

Regarding the etiology, Hall stated that the first fungus to be isolated from ears was identified as an *Aspergillus* by Prof. Schwartz of Halle (Hall, 1877). *Aspergillus fumigatus* was cited in a paper of Whale (1915) and *Mucor mucedor* is described in McKenzie (1926). One of the first etiological classifications of otomycosis appeared with Wolf, who created a list of fungi responsible for this pathology: Aspergillaceae (*Aspergillus*, *Penicillium* and *Scopulariopsis*), Mucoraceae (*Lichtheimia*, *Mucor*, *Rhizopus* and *Syncephalas-trum*), Yeast-like fungi, Dermatophytes, Actinomycetaceae and miscellaneous (Wolf, 1947). Haley distinguished from kinds of fungi isolated from normal ears in contrast with those isolated from infected ears (Haley, 1950).

From the 1950s until the 1990s, attention has been drawn to the increasing problem of otomycosis and its prevalence (Blank and Stuart, 1955; Holt and Morgan Jr, 1958; Gregson and La Touche, 1961; Sood et al., 1967; Youssef and Abdou, 1967a,b; Yamashita and Yamashita, 1972; Yassin et al., 1978; Mugliston and O’Donoghue, 1985; Chow and Ho, 1986), pointing out especially cases of aspergillosis and dermatophytosis of the external auditory meatus (Stuart and Blank, 1955; English, 1957; Ismail, 1962; Yassin et al., 1964; Watanabe, 1986; Stern and Lucente, 1988), despite some authors denying the existence of this pathological entity—“*Infections of the ear with pathogenic fungi have something in common with the snakes of Ireland; there are none*”—(Kingery, 1965).

The first experiments were conducted to explain the increased incidence of otomycosis during the warm seasons, finding that there are some factors that equally contribute together in the etiology: the pH value, the incubation temperature, the humidity and the alkalinity of water supply (Ismail, 1962; Yassin et al., 1964). Furthermore, some authors redefined the term otomycosis to include fungal infection of the external ear, middle ear and open mastoid cavity (Yassin et al., 1964; Paulose et al., 1989).

Otomycosis of the external ear

In terms of superficial infections, otomycosis represents about the 10–30% of the all the affections related to the external auditory meatus (EAM) (Pontes et al., 2009; Alarid-Coronel et al., 2018).

Risk factors

The anatomy of the EAM simulates a culture medium with skin that guarantees ideal conditions for fungal growth, and a narrow auditory canal facilitates the development of otomycosis, especially if is associated with eczema and dermatitis (Prasad et al., 2014). Furthermore, warm and humid climate, the use of earphones/earplugs, swimming in polluted waters, self-injury (Yassine and Haiet, 2018), metabolic disorders and/or immunodeficiencies (Patel et al., 1999; Viswanatha and Naseeruddin, 2011; Viswanatha et al., 2012),

malnutrition, abuse of topical eardrops (Schrader and Isaacson, 2003; Jackman et al., 2005) represent well known risk factors (Enweani and Igumbor, 1997; Tasić-Otašević et al., 2020), even if fungal organisms (especially *Candida* spp.) may be isolated from cases of otitis externa without risk factors for fungal infections (Enoz et al., 2009).

Geography

Prevalence of otomycosis in tropical and humid environments, particularly during rainy months, has been described by many authors (Stern and Lucente, 1988; Paulose et al., 1989; Pontes et al., 2009; Prasad et al., 2014; Gughani et al., 1989; Ozcan et al., 2003a,b; Kumar, 2005; Fasunla et al., 2007; Aneja et al., 2010).

Regarding otomycosis' epidemiology, this pathology is widespread worldwide (Yehia et al., 1990; Zaror et al., 1991; Pradhan et al., 2003; Dorko et al., 2004; Jia et al., 2012; Adoga and Iduh, 2014; Ismail et al., 2017; Li and He, 2019), and many studies were conducted in Middle East countries, especially Iran (Barati et al., 2011; Saki et al., 2013; Nemati et al., 2014; Kiakojuri et al., 2015; Gharaghani et al., 2015; Kazemi et al., 2015; Abastabar et al., 2019; Aboutalebian et al., 2019; Sabz et al., 2019; Kamali Sarwestani et al., 2019).

Sex, occupation and age

The gender prevalence is heterogeneous: some authors report that otomycosis was seen in women more than in men (Yehia et al., 1990; Fasunla et al., 2007; Pontes et al., 2009; Aneja et al., 2010; Barati et al., 2011; Jia et al., 2012; Kiakojuri et al., 2015; Nemati et al., 2014; Fayemiwo et al., 2010), others say the opposite (Mugliston and O'Donoghue, 1985; Pradhan et al., 2003; Yehia et al., 1990; Prasad et al., 2014; Garcia-Martos et al., 1993; Vennewald and Klemm, 2010; Garcia-Agudo et al., 2011; Degerli et al., 2012; Agarwal and Devi, 2017).

The highest incidence of otomycosis was found inside rural communities (Prasad et al., 2014; Agarwal and Devi, 2017; Abdelazeem et al., 2015) and in people of lower socioeconomic status (Barati et al., 2011; Aneja et al., 2010). The mean age was estimated between 21 and 30 years old by Prasad et al. (2014), and between 15 and 35 years old for Agarwal and Devi (2017), but Jackman et al. (2005) reported that "the number of paediatric patients diagnosed with otomycosis has increased over the past decade" (Westby et al., 2020).

Microbiology

Among the latest studies focused on causative fungal pathogens of external otitis, we find respectively those conducted by Abastabar et al. (2019), Aboutalebian et al. (2019), Rath et al. (2019), Sabz et al. (2019) and Tasić-Otašević et al. (2020).

The most frequent fungi associated with otomycosis are *Aspergillus* spp. and *Candida* spp. (Abdelazeem et al., 2015; Agarwal and Devi, 2017; Jadhav et al., 2003; Ozcan et al., 2003a,b; Hueso Gutiérrez et al., 2005; Ali et al., 2018; Hagiwara et al., 2019; Tasić-Otašević et al., 2020). Regarding *Aspergillus* spp., many updated molecular studies found black *Aspergillus* species other than *A. niger* as the most frequent causative agents (Szigeti et al., 2012; Kamali Sarwestani et al., 2018), that is in contrast with the previous known microbiological spectrum of otomycosis. In this sense, molecular studies should be mandatory to provide specific results related to the microbial epidemiology of fungal infections of the ear. According to Aboutalebian et al. (2019), if sequence analysis had not been adapted, basing on morphology, all isolated *A. tubingensis*, *A. niger*, *A. awamori*, *A. foetidus*, etc. would be identified as *A. niger*, making this organism the most frequent genera. In fact recently Sabz et al. (2019) demonstrated that, in their analysis, *A. tubingensis* was the dominant causative agent of otomycosis.

Some researches prove non-albicans *Candida* species domination, at first place *C. parapsilosis* followed by *C. guilliermondii*, *C. glabrata*, *C. tropicalis* (Kurnatowski and Filipiak, 2001; Garcia-Agudo et al., 2011; Aboutalebian et al., 2019); the majority of *Candida* strains isolated are protease positive (Arsović et al., 2009). Moreover, *C. auris* has been proven to be an emerging otomycotic pathogen (Abastabar et al., 2019; Satoh et al., 2009; Pekard-Amenitsch et al., 2018).

Combined infections (*Aspergillus* + *Candida*) must also to be taken into consideration, even if they are demonstrated in only the 5.5% of patients (Tasić-Otašević et al., 2020). In this group, recurrences and chronic entities may be avoided choosing the right drugs' combination, effective against both yeasts and molds (Jia et al., 2012).

Regarding less common pathogens, we find *Exophiala dermatitidis* (Kerkmann et al., 1999), *Trichoderma longibrachiatum* (Hennequin et al., 2000), *Trichophyton rubrum* (Buzina et al., 2004), *Aspergillus sclerotiorum* (Harima et al., 2004), *Malassezia* spp. (Latha et al., 2010) *Chaetomium brasiliense* (Hubka et al., 2011), *Pseudallescheria apiosperma* (Neji et al., 2013), *Scedosporium apiospermum* (Huguenin et al., 2015; Salamat et al., 2015), *Schizophyllum commune* (Matos et al., 2016; Maeda et al., 2019), *Scedosporium prolificans* (Wen et al. 2016), *Saksenaea vasiformis* (Trabelsi et al., 2020).

Signs and symptoms

Even if fungi were often isolated in patients without clinical signs of fungal infection (Saunders et al., 2011), symptoms of otomycosis include otalgia, itching, hearing loss and tinnitus (Ho et al., 2006; Anwar and Gohar, 2014), while signs of fungal infection could be otorrhoea and discharge. Aspergillosis is characterized by the presence of large keratinic scales with a sort of wet tissuepaper aspect. Typically the manifestation of *A. niger* includes black tufts and spots (Fig. 1), while *A. fumigatus* looks greenish.

Fig. 1 Otoscopic view of external otomycosis (*A. niger*).

Candida usually provokes a significant edema of the EAM with skin maceration and white creamy secretions; much more rarely otomycosis could occur with aural mass (Patel et al., 1999; Hoshino and Matsumoto, 2006). Ear fungal infections can also lead to tympanic membrane perforations (Pradhan et al., 2003; Jia et al., 2012; Hurst, 2001; Abou-Halawa et al., 2012; Song et al., 2014) and sometimes the presentation is bilateral (Mishra et al., 2004; Kirschner et al., 2017).

We can divide fungal infections in:

- Primary otomycosis (in the EAM of an immunocompetent patient, no tympanic membrane perforation, no middle ear pathology)
 - a) without external otitis
 - b) with external otitis, previously absent (that is, due to otomycosis and not vice versa)
- Secondary otomycosis (pre-existing otitis media or externa, history of trauma and/or otosurgery, history of and/or fungal infection of other anatomical districts)
 - a) without immunocompromise
 - b) with immunocompromise (Prasad et al., 2014).

Diagnosis

Apart from patients' history and direct otoscopy, conventional diagnostic methods include microscopic examination of the samples and also immunofluorescence microscopy (Gurr et al., 1997), but the gold standard is represented by detection and identification of the source of fungal infection through the culture of ear secretions on specific growth media (Tasić-Otašević et al., 2020). In well-equipped Units, antimycogram is done to study sensitivity of strains to drugs in vitro. However, recent researches are focused on molecular diagnosis (Hagiwara et al., 2019) and matrix-assisted laser desorption ionization time of flight mass spectroscopy (Rath et al., 2019). Radiologic studies as computed tomography and resonance magnetic imaging are more useful in case of suspected fungal malignant external otitis and fungal middle ear otitis (see below).

Fungal malignant external otitis

The first detailed reports of fungal malignant external otitis (FMEO) are described in 1985 by Petrak et al. (1985), Bickley et al. (1988) and Cunningham et al. (1988)—although, a report of mixed *Serratia* and *Aspergillus* infection has been briefly mentioned in a series from Fisher et al. (1981). Invasive external otitis generally occurs in patients with underlying pathologies (diabetes, immunodeficiencies, hematologic illnesses, etc.): this applies both for bacterial (especially *Pseudomonas aeruginosa*) and fungal forms (Petrak et al., 1985; Bickley et al., 1988; Cunningham Phillips et al., 1990; Reiss et al., 1991); among other things, these two forms can be added together (Bovo et al., 2012).

FMEO is characterized by an aggressive infection that develops from the EAM and spreads along the soft tissues (Noroy et al., 2020) and bones of the skull base (Chandler, 1968). Symptoms are non-specific and include ear pain, otorrhea, hearing loss and

possible facial nerve palsy (Lilic et al., 2012; Walton and Coulson, 2014). From a demographic point of view, FMEO affects in primis elderly diabetic patients (Tarazi et al., 2012), the 75% of which present intense otalgia, especially during night (Bovo et al., 2012) while purulent otorrhea ranges from 50% and 80% of the cases (Bovo et al., 2012). The histologic examination typically shows granulation tissue with non-specific signs of inflammation (Bovo et al., 2012).

Computed tomography and magnetic resonance imaging can document swelling of the EAM, involvement of the mastoid, bones erosion, tissue infiltration and/or complications as skull base osteomyelitis and abscesses (Pichon et al., 2020), on the basis of the stage of the pathology (from a limited infection of the EAM and the nearby soft tissue, to a non-complicated osteitis or mild cranial nerves neuropathies, to infiltration of intracranial structures and neck spaces). Technetium Tc 99m, methylene diphosphonate scintigraphy (bone scan) result positive in almost 100% of MEO, allowing early diagnosis of osteomyelitis. Gallium citrate Ga 67 accumulates in soft tissues' inflammation and bone infections and can be beneficial in the diagnosis recurrent disease (Vennwald and Klemm, 2010).

The most common causative pathogens are *Aspergillus* spp.: after *A. fumigatus* (van Tol and van Rijswijk, 2009; Clark et al., 2011), *A. flavus* is the second mycotic cause (Pichon et al., 2020; Hedayati et al., 2007); less frequent are *A. niger* (Bellini et al., 2003; Zriba et al., 2014) and *A. wentii* (Halsey et al., 2011), followed by *Candida* spp. (Bae et al., 2007; Mani et al., 2008; Hamzany et al., 2011; Elayoubi et al., 2016). Much more rarely we find *Malassezia sympodialis* (Chai et al., 2000), *Scedosporium apiospermum* (Yao and Messner, 2001; McLaren and Potter, 2016; Doss and Doss, 2018), mucormycosis (Tuzcu et al., 2006) and *Scopulariopsis brevicaulis* (de Miguel-Martinez et al., 2018).

The diagnosis of FMEO is often delayed:

- generally, anti-pseudomonal treatment is started even if the bacterial samples don't show growth, so frequently it takes a long time to change management strategy;
- culturing fungi from tissue-collected specimens yields a very low rate of positive results;
- there isn't clear clinical, laboratory or radiological finding that allows to differentiate fungal from bacterial infection, except for tissue sampling for direct smear or polymerase chain reaction (Gruber et al., 2015), and specific fungal cultures. (Abu Eta et al., 2018).

Thus, culture of biopsy samples and histologic examination are mandatory in cases of persistent ear pain that resists to apparently appropriate antimicrobial therapy (Pichon et al., 2020; Gordon and Giddings, 1994).

The consequence of FMEO can be dramatic, with described dissemination from the ear to other organs (Harley et al., 1995), skull base osteomyelitis (Shelton et al., 2002) and jugular thrombosis (Moniot et al., 2019).

About the therapy, it will be discussed in more detail later: generally, the treatment can include conservative solutions (Finer et al., 2002; Ling and Sader, 2008; Marchionni et al., 2016), sometimes in association with more aggressive approaches (Marzo and Leonetti, 2003).

It was demonstrated that the efficacy of FMEO therapy depends on the assessment of cranial nerve state, the causative pathogen and imaging findings: absence of facial nerve palsy, *Aspergillus* spp. and absence of radiological signs correlate with better prognosis (Mion et al., 2015).

Fungal otitis media

Smyth evidenced that "Towards the end of 1956, fungi were repeatedly isolated from a high proportion of chronically infected postoperative mastoid cavities", pointing out the relevance of fungal infections of the middle ear (Smyth, 2006).

Those at greatest risk are agricultural field workers (Wadhvani and Srivastava, 1984) and immunocompromised patients: in this last group, *Pneumocystis carinii* is particularly common as causative pathogen (Gherman et al., 1988; Smith et al., 1988; Sandler et al., 1990; Park et al., 1992; Menger and v d Berg, 2003). Other fungi responsible for middle ear infections are *Aspergillus* spp. (Talwar et al., 1988; Hall and Farrior, 1993; Chen et al., 1999; Tiwari et al., 1995; Ibekwe et al., 1997; Yates et al., 1997; Juyal et al., 2014) that can affect predisposed subjects as in case of autoimmune disease (Amonoo-Kuofi et al., 2005), but also immunocompetent patients (Ohki et al., 2001; Youssef et al., 2014); *Candida* spp. alone (Kurnatowski and Filipiak, 2001; Martin et al., 2005; Choi et al., 2017) or in association with *Aspergillus* spp. (Punia et al., 2019). More rarely we find *Scedosporium apiospermum* (Bhally et al., 2004; Baumgartner et al., 2007; Koay et al., 2015), *Blastomyces dermatitidis* (Istorico et al., 1992; Nguyen et al., 2013), *Apophysomyces elegans* (Goyal et al., 2007), entomophthorales (Arya et al., 2011) and *Paracoccidioides brasiliensis* (Lucinda and Polanski, 2017).

Two cases of fungal allergic otomastoiditis have been described (Chen and Chiang, 2013; Salamah and Al-Shamani, 2019), showing the existence of allergic reactions to fungi in the middle ear, as well as the presence of fungal hyphae have been demonstrated in fluids collected from eosinophilic otitis media (Murakami et al., 2012); furthermore, fungal colonizations of cholesteatoma are documented (Singh et al., 2018).

Age ranges from childhood to elderly subjects; signs and symptoms don't differ from those of classic middle otitis, as well as imaging findings—for instance, presence of soft tissue density in the mastoid antrum, mastoid air cells and/or in the middle ear, with or without destruction of tegmen tympani—(Punia et al. 2019).

The complications of fungal middle otitis can be very serious: from otomastoiditis and tympanic membrane perforations (Koltsidopoulos and Skoulakis, 2020) to skull base osteomyelitis (Menachof and Jackler, 1990; Stodulski et al., 2006; Marechal et al., 2018), petrous apicitis (Rushton et al., 2004; Eloy et al., 2007; Bhatt et al., 2013) and meningitis (Morgand et al., 2015; Okada et al., 2015). Specific resistance allele found in some strains of fungi can explain the aggressiveness in certain infective forms (Mushi et al., 2016; Zhang et al., 2020).

The diagnosis is usually performed using samples of discharge from middle ear (directly in cases of tympanic membrane perforation or intra-operatively during mastoidectomy), then the mycological examination can be conducted by microscopy, fungal cultures and polymerase chain reaction (Kim et al., 2002; Vennewald et al., 2003).

The histologic examination of surgical specimens can highlight:

- fungal hyphae in the stratum corneum of EAM's epithelium, in the middle ear's cavity or between the lamelle of cholesteatomas;
- chronic hyperplastic/polypoid inflammation of the middle ear's mucosa;
- growth of mycelium in blood vessels and bones (Vennewald and Klemm, 2010).

Fungi in the inner ear

The literature documents only a case of fungal invasion of the inner ear: Haruna et al. (1994) describe the presence of *Mucor* species within internal auditory nerve found during the autoptical examination of a patient died for acute myelogenous leukemia.

Treatment of otomycosis

In 1948, Bryant wrote a "Do nots" list from the observation of 4600 cases of otomycosis:

1. Do not neglect to cleanse the ear thoroughly.
2. Do not neglect to ascertain the presence of acute external otitis by otoscopy and by manipulation of the auricle and pressure on the tragus.
3. Do not treat the otomycosis until the superimposed acute external otitis has been treated and cured.
4. Do not treat otomycosis without first removing all exudate and debris.
5. Do not hesitate to use aqueous solutions for irrigating.
6. Do not neglect to dry the canal thoroughly.
7. Do not use colored preparations in the treatment of the ear at any stage.
8. Do not discontinue the prescription used for otomycosis until 6 weeks have elapsed following cessation of all symptoms and signs.
9. Do not presume that every ear canal containing moist debris indicates mycosis, for all is not mold that litters (Bryant, 1948).

In consideration of the fact that the first studies showed *Aspergillus* spp. as the main causative pathogens, Damato reported the great efficacy of topical Tolnaftate against *A. niger* (Damato, 1973), while Schönebeck and Zakrisson demonstrated the value of topical 5-fluorocytosine (Schönebeck and Zakrisson, 1974)—result confirmed few years later by Lopez and Evens (1980). Cresylate revealed non-specific antimicrobial activity, while nystatin and mostly clotrimazole showed specific antifungal power (Lawrence et al., 1978; Maher et al., 1982; Bassiouny et al., 1986; Stern et al., 1988). Clotrimazole drops, miconazole cream and fluconazole drops showed same therapeutic efficacy (Navaneethan and Yaadhava Krishnan, 2015), furthermore topical use of clotrimazole alone (Abou-Halawa et al., 2012; Dundar and İylen, 2019) or in association with ceftizoxime powder (Mahdavi Omran et al., 2018) appears safe also for otomycosis with tympanic membrane perforations and seems to be more powerful than tolnaftate as a therapy (Jimenez-Garcia et al., 2020) and in the prevention of infections' recurrences (Kiakojuri et al., 2019)—that are estimated around the 7.3%—(Kiakojuri et al., 2018).

About the effect of Aqueous Merthiolate, someone believed that this solution has not specificity against fungi (Lawrence et al., 1978; Stern et al., 1988), others reported a sure effect against otomycosis (Lopez and Evens, 1980; Schneider, 1981).

Some researches are focused on more natural remedies (alone or with a synergistic effect with antifungal drugs) as fixed oils treated with herbal seeds (Jain et al., 1993), garlic extract (Pai and Platt, 1995), volatile vapours of perfumes as musk and jasmine (Jain and Agrawal, 2002) and other organic volatile substances (Jain and Agrawal, 1994), honey and starch (Boukraâ and Bouchehrane, 2007), *Aloe Vera* leaf extract (Saniasiya et al., 2017), thyme oil and clove extracts (Ghaly et al., 2020).

Applications of mercurochrome are suggested in case of external otomycosis (Chander et al., 1996; Mgbor and Gugnani, 2001), while boric acid seems to be less effective compared to other solutions as ciclopiroxolamine and clotrimazole (del Palacio et al., 2002; Romsaithong et al., 2016).

Povidone iodine applications appear valid also against recalcitrant forms of external otomycosis (Philip et al., 2013; Swain et al., 2018; Mofatteh et al., 2018).

Hyperbaric oxygen is useful especially in cases of FMEO, probably for the microangiopathy typical of diabetic patients with the consequent local hypoxia and ischemia: necrotizing inflammation of soft tissues and resistance to osteomyelitis treatment are generally accepted indications for hyperbaric oxygen therapy (Narozny et al., 2006), and many studies proved its efficacy against FMEO due to *Aspergillus* spp. (Bellini et al., 2003; Yao and Messner, 2001; Shelton et al., 2002; Finer et al., 2002).

Regarding in vitro investigations, terbinafine seems to be valid against otomycosis (Rotoli et al., 2001; Karaarslan et al., 2004; Zarei Mahmoudabadi et al., 2015; Yang and Young, 2019) and the last researches confirm these data also with clinical trials (Xu et al., 2020). Isolated studies were conducted on luliconazole (Moslem and Mahmoudabadi, 2020) and clioquinol (Cimolai, 2020).

Munguia and Daniel propose a detailed review of the main ototopical antifungal drugs, finding that the azoles class such as clotrimazole, fluconazole, ketoconazole and miconazole are more effective, followed by nystatin and tolnaftate (Munguia and Daniel, 2008); fluconazole exhibited broad spectrum effect *Aspergillus* spp. and *Candida* spp. (Ahmed et al., 2018).

Many studies were performed on voriconazole: Ayçiçek et al. proved that caspofungin and voriconazole in vitro are effective as amphotericin B and itraconazole (Ayçiçek et al., 2009), even if Kaya et al. found that some *A. fumigatus* and some *A. niger* result resistant against itraconazole (Kaya and Kiraz, 2007), furthermore voriconazole has been shown more potent in vitro than itraconazole (Yenişehirli et al., 2009). In vivo, local application of a 1% sterile solution of voriconazole resulted successful in the treatment of nystatin-resistant *A. niger* otomycosis (Chappe et al., 2018). Oral voriconazole is extensively used also in FMEO (with surgical debridement where required), as demonstrated by many reviews of the literature (Mion et al., 2015; Parize et al., 2009; Ho et al., 2014): the administered doses depend on the stage and the gravity of the infection.

In summary, superficial otomycosis and chronic colonization should be treated with cleansing and debridement under otomicroscopic vision associated with ototopical antifungal drugs (solutions, creams, drops, oil, gel, etc.). Given the possibility of tympanic membrane perforations, low risk of ototoxicity is a fundamental property of the chosen topical treatment, waiting for application of paper patches or waiting to perform cartilage myringoplasty (both are suitable solutions in front of perforations with otomycosis) (Görür et al., 2019; Lou, 2020).

Systematic therapy should be reserved for severe cases, as fungal middle otitis with mastoiditis or other complications, and for FMEO with important inflammation of the soft tissues and the bones; in this last situation, glycemic control is mandatory. Nowadays, early antimycotics as ketoconazole and amphotericin B have been replaced with fluconazole and voriconazole, orally and intravenously administrable. The triazoles should be preferred for mastoiditis and otogenic cerebral mycosis given their low molecular weight (Vennewald and Klemm, 2010). Voriconazole has very good penetration of bone and synovial fluid, that is essential in case of fungal mastoiditis or otogenic meningitis (Vennewald and Klemm, 2010).

Glossary

Infestation Arthropods living in or on a person as a parasite.

Maggot Fly larva.

Myiasis Parasitic infestation of live animals by dipterous fly larvae.

The human ear is a fascinating organ of hearing and equilibrium, which is only rarely involved in parasitic infections. Most parasitic infections occur in the outer portion of the ear, as this is the area that communicates with the outside world. The short external auditory canal may be entered by a variety of arthropods, and while many are not capable of surviving in this environment, some such as parasitic fly larvae and mites may cause patent infestations. There have also been rare reports of infection of the outer ear canal with free-living nematodes in the genus *Rhabditis* (Teschner et al., 2014). The auditory canal ends with the tympanic membrane (ear drum) which separates the outer and middle portions of the ear and presents a thin, delicate barrier against inward parasite invasion. The middle ear is a narrow, air-filled cavity in the temporal bone which contains three tiny bones involved in sound conduction from the tympanic membrane to the inner ear. Parasites may enter the middle ear through a ruptured tympanic membrane, through the Eustachian tube, or by direct invasion from neighboring structures. As the middle ear is connected to the nasopharynx through the Eustachian tube, migrating worms such as *Ascaris lumbricoides* (Fagan and Prescott, 1993; Jain and Pahuja, 1988; Maqbool, 1975), and possibly *Enterobius vermicularis*, may rarely pass into the middle ear from the gastrointestinal tract and cause acute otitis media and associated physical damage. *Ascaris lumbricoides* and *E. vermicularis* are covered in greater detail elsewhere, and therefore will not be covered in this chapter. The innermost portion of the ear is referred to as the inner ear, and houses the vestibular system (involved in balance) and cochlea (the organ of hearing). Worms such as *Lagochilascaris minor*, and rarely, *Gnathostoma* spp. (Cutchavaree et al., 1985), may invade any part of the outer, middle and inner ear as it migrates throughout the head and neck.

This chapter will cover the most common parasitic infections and infestations of the ear: aural myiasis (otomyiasis), otoacariasis, and lagochilascariasis. The biology of each parasite will be described, along with the clinical manifestations, diagnosis and treatment of the associated infection or infestation.

Aural myiasis (otomyiasis)

Biology and epidemiology

Aural myiasis, also known as otomyiasis, is the infestation or colonization of the ear by dipterous fly larvae. There are different ways to classify myiasis, with the most common being based on anatomic and ecological features (Francesconi and Lupi, 2012; Mathison and Pritt, 2014, 2015). When considering its anatomic classification, aural myiasis is characterized as a form of cavitary myiasis, in which a cavity such as the ear canal, nose, eye or brain is infested by larvae (Francesconi and Lupi, 2012). Since aural myiasis commonly involves a pre-existing wound or diseased tissue, it may also be characterized as a form of wound myiasis, particularly when the wound involves the outer earlobe (auricular or pinna). The ecological classification of myiasis considers the nature of the

infesting larvae, and whether they are obligatory, facultative or accidental parasites. Obligatory parasites require a human host to complete their lifecycle and readily invade healthy tissue. In contrast, facultative parasites are free-living, and usually feed on dead and decaying matter in the environment. They may become parasites when they colonize pre-existing wounds and feed on decaying tissue (Mathison and Pritt, 2014). Occasionally facultative parasites will attack healthy tissue as well. Accidental or incidental myiasis, sometimes referred to as pseudomyiasis, occurs when free-living larvae incidentally colonization mucus membranes or biofilms on invasive medical devices, such as catheters. They do not feed on host tissue, but may cause a pathological host reaction from their presence.

Cases of aural myiasis have been reported from around the world, with most cases being found in tropical climates. Both obligatory and facultative parasites have been implicated, with *Cochliomyia hominivorax* (New World screwworm fly), *Chrysomya bezziana* (Old World screwworm fly), *Chrysomya megacephala* (latrine fly), *Wohlfahrtia magnifica* (spotted flesh fly), *Sarcophaga* spp. (Oriental flesh fly) being the important agents (Francesconi and Lupi, 2012) (Fig. 1 and Table 1).

Dipterous flies have four life cycle stages: egg, larva, pupa and adult (Mullen and Durden, 2019). Aural myiasis begins when eggs or larvae are deposited near the aural cavity or in pre-existing wounds involving the ear and neighboring structures (Francesconi and Lupi, 2012). Eggs hatch to release first instar larvae. If left undisturbed, the larvae will feed on living and/or dead tissue and molt into second, and eventually third, instar stages. In nature, the third stage larva will leave the host to form a pupa, from which the adult fly eventually emerges. The entire lifecycle spans a period of several weeks and may vary based on the temperature and humidity.

Clinical presentation, pathology, and treatment

The clinical presentation of aural myiasis varies with the location and extent of the infestation. As larvae feed on decaying and/or healthy tissue, patients may experience ear pain, bleeding, malodorous discharge, restlessness, foreign body sensation, tinnitus, vertigo, and impaired hearing. Larvae are observed within the ear, or crawling out of the ear canal (Francesconi and Lupi, 2012; Hernando et al., 2017). Diffuse erythema and edema of the external auditory canal, and perforation of the tympanic membrane may also be noted on otological examination (Francesconi and Lupi, 2012). Most cases of aural myiasis have been reported in young children (including neonates) (Casanova-Roman et al., 2010; Yuca et al., 2005; Al Jabr, 2015; Tligui et al., 2007), patients with preexisting aural disease, and debilitated individuals (e.g., intoxicated, physically or mentally disabled) (Francesconi and Lupi, 2012; Werminghaus et al., 2008; Magliulo et al., 2000; Jiang et al., 2020). Poor hygiene and socioeconomic status have been identified as risk factors (Hernando et al., 2017). Chronic otorrhea may also be a risk factor, particularly in otherwise healthy individuals (Arora et al., 2009; Yuca et al., 2005). The infestation is nearly always unilateral, although rare cases of bilateral disease have been reported (Bayindir et al., 2010; Yuca et al., 2005).

If untreated, the infestation may lead to destruction of the middle ear, deafness, invasion of the mastoid cavity, penetration of the central nervous system, and rarely, death (Francesconi and Lupi, 2012; Arora et al., 2009). Infection with larvae causing obligatory myiasis are of particular concern (e.g., *C. hominivorax*, *C. bezziana*), given their ability to actively invade healthy tissue and cause wide-spread damage. Radiologic imaging such as computed tomography is helpful for assessing the extent of invasion. Treatment is by removal of the larvae by ear irrigation, suction, and otoscopic and/or surgical extraction. Cases involving the middle ear or mastoid may require extensive debridement and multiple procedures to ensure removal of all larvae (Francesconi and Lupi, 2012; Uzun et al., 2004). Antibacterial agents are also commonly administered to prevent bacterial superinfection.

Fig. 1 Third instar larva of *Cochliomyia hominivorax*, an important cause of aural myiasis in Latin America. The overall body shape, arrangement of the cuticular spines, and features of the posterior spiracles are used for identifying the dipterous fly larvae. The third instar larva of *C. hominivorax* has an elongate, screw-shaped body with cuticular spines on all body segments, and the spiracular plate (inset) has three relatively-straight slits that point toward the opening of the peritreme (plate that surrounds the spiracles). From Mathison BA and Pritt BS (2015) Arthropod Benchtop Reference Guide. Northfield, IL: College of American Pathologists, used with permission.

Table 1 Flies implicated in aural myiasis with select references (the references are not necessarily exhaustive for a given species).

Genus and species	Geographic location	Reference(s)
Facultative myiasis		
<i>Calliphora</i> spp.	India	Bapat (2000) and Jain et al. (2008)
<i>Chrysomya megacephala</i>	Malaysia	Lee and Yong (1991)

<i>Wohlfahrtia magnifica</i>	Saudi Arabia, Turkey; Egypt, Morocco, Spain, Italy	Al Jabr (2015), Ata and Güzelkara (2017), Karaman et al. (2009), el Kadery and el-Begermy (1989), Tligui et al. (2007), Casanova-Roman et al. (2010), Atmaca et al. (2009), Uzun et al. (2004), Bayindir et al. (2010), and Magliulo et al. (2000)

Diagnosis

Diagnosis of aural myiasis is made by finding fly larvae within the ear. As removal is curative, the specific identification of the infesting fly may not be necessary, except when investigating the route in which the infestation was acquired (Francesconi and Lupi, 2012). Fly larvae are identified based on the geographic distribution and several morphologic features such as the overall body size and shape, arrangement of the cuticular spines, and form of the posterior spiracles (Mathison and Pritt, 2014, 2015).

Otoacariasis

Biology and epidemiology

Otoacariasis is infestation of the ear canal with mites and ticks. Several species of ticks and mites have been implicated in otoacariasis, and while uncommon, the condition can occur anywhere in the world (Table 2).

The most common agents associated with otoacariasis are hard ticks (family Ixodidae), including members of the genera *Amblyomma*, *Dermacentor*, *Haemaphysalis*, *Hyalomma*, *Ixodes*, and *Rhipicephalus*. Ticks in these genera are typically zoonotic on humans and their presence in the ear canal is usually incidental and atypical.

One species of soft tick (family Argasidae) that is adapted to feed in the ear canals of its mammalian hosts, *Otobius megnini*, causes rare zoonotic infections in humans. *Otobius megnini* has a one-host life cycle. Natural hosts are primarily ungulates, such as cattle, goat, sheep, deer, and horses, but other mammals can be infected. Native to western North America, *O. megnini* now occurs nearly worldwide where livestock is raised. Only larvae and nymphs feed on the vertebrate host, and stay attached for prolonged periods of time; adults live off the host and do not feed. The number of nymphal stages in the life cycle is unresolved and various studies have proposed one, two, or three nymphal instars (Rajakaruna and Diyes, 2019). *Otodectes cynotis*, the common ear mite of pets (especially cats) can also rarely cause infections in humans, usually among people with poor hygiene practices or who have prolonged exposure to infected natural hosts (Van de Heyning and Thienpont, 1977).

A number of other mites, that either parasitize non-human animals or are free-living in the environment, have been implicated in human otoacariasis, including members of the genera *Dermanyssus*, *Cosmoglyphus*, *Sancassania*, *Rhizoglyphus*, *Chorotoglyphus*, and even household dust mites in the genus *Dermatophagoides*. Most of these are self-limiting following proper control measures.

Clinical presentation, pathology, and treatment

When symptoms are present, the most common complaint of otoacariasis is acute ear pain. Other symptoms include dizziness, tinnitus, bleeding, hearing loss, facial paresis, otitis externa and otitis media. Toxins in the tick's saliva may induce facial or respiratory paralysis or facial palsy (Cakabay et al., 2016). Patients may report hearing unusual sounds, such as crackling in the ear (Grady et al., 2011). Physical trauma can result in rupturing of the tympanic membrane. Symptoms usually wane after successful removal of the tick. However, it is possible in some cases that physical trauma and pain may be caused more by haphazard removal of the tick rather than the host reaction to the tick.

Table 2 Mites and ticks implicated in otocariasis with select references (the references are not necessarily exhaustive for a given species).

Species	Geographic location	Reference(s)
Family: Ixodidae (hard ticks)

Family: Histiostomatidae (histiostomatid mites)		
Histiomatidae, gen. sp.	Saudi Arabia	Al-Arfaj et al. (2007)

In areas that are endemic for tickborne pathogens, ticks in the ear may vector disease-causing agents, including those responsible for Lyme disease, Rocky Mountain spotted fever, ehrlichiosis, anaplasmosis, Crimean-Congo hemorrhagic fever, and babesiosis.

Treatment for otoacariasis is the successful removal of the offending agents, especially with ticks that are larger and generally visible to the naked eye. For mites, topical solutions can be used to kill and flush out the mites. A 2% solution of hydrogen peroxide was used to successfully treat a case of otoacariasis caused by mites in the genus *Rhyzoglyphus* (Kiakojouri et al., 2018). Ear drops containing crothamiton were used to treat an unidentified histiostomatid mite (Al-Arfaj et al., 2007). One percent permethrin was used to treat a case of otoacariasis caused by a mite in the genus *Cosmoglyphus* (Pal et al., 2018). A case of otoacariasis caused by the common dust mite *Dermatophagoides pteronyssinus* was successfully treated using eardrops containing triamcinolone, nystatin, neomycin, and gramicidin (Liao and Chang, 2012). These topical solutions are often complimented with oral antibiotics, also to prevent secondary bacterial infections in the lesions caused by the ticks as well as to preemptively treat bacterial pathogens that may have been transmitted by the arthropod.

Diagnosis

Diagnosis of otoacariasis is by the morphologic identification of the ticks and mites removed from the ear. Removal is generally curative, and a definitive identification may not be necessary, except when determining the risk for tickborne diseases endemic to where the tick was acquired (Cakabay et al., 2016).

Lagochilascariasis (*Lagochilascaris minor*)

Biology and epidemiology

Lagochilascariasis is caused by the rare zoonotic nematode *Lagochilascaris minor*. The parasite occurs throughout Central and South America. Natural hosts are presumed to be wild felines. Prior to 2016, *L. minor* was only documented from humans until a wild mountain lion was found parasitized in Mexico (Falcon-Ordaz et al., 2016). Human cases have been documented in Mexico, Costa Rica, Suriname, Trinidad and Tobago, Bolivia, Colombia, Venezuela, Ecuador, Paraguay, Peru, and Brazil; over 70% of the cases in the literature come from Brazil (Campos et al., 2017).

The natural life cycle is still unknown; however, experimental models using cats and mice suggest a two-host life cycle whereby the feline definitive host becomes infected after consuming infected intermediate hosts. The sources of human infection are not known, but it is believed humans become infected after eating undercooked meat, especially that of rodents such as cavies, agoutis, and Guinea pigs (Campos et al., 2017).

Clinical presentation, pathology, and treatment

The most common clinical presentation of lagochilascariasis is the presence of a subcutaneous abscess on the neck, middle ear, tonsils, mastoid, and sinuses. Other sites of infection include lungs, eyes, and central nervous system (Campos et al., 2017). Patients may present with the sensation of moving in the throat and the discharge of young adult and mature worms from the nose, throat, and ears (Orihel and Ash, 1995). The presence of multiple parasite stages (eggs, larvae, adults) in some sites suggests the possibility of autoinfection in the human host (Campos et al., 2017; Orihel and Ash, 1995).

Aural involvement of *L. minor* usually presents as an ulcer in the middle ear with discharge. Perforation of the tympanum can occur and young adult or mature worms are often expelled from the ear canal. Aural infection can often be secondary to other areas of the head and neck and may present as Gradenigo's syndrome (Douma et al., 2016).

Several drugs have been used in cases of lagochilascariasis. Treatment often multiple anthelmintic agents and is initiated with thiabendazole, followed by either diethylcarbamazine (DEC) or mebendazole, and then lastly with levamisole. In some cases surgical removal may be warranted (Campos et al., 2017). Left untreated, infection can last years.

Diagnosis

Lagochilascariasis is usually diagnosed by the morphological identification of expelled worms or histopathologic examination of biopsy specimens (Fig. 2).

Adult female worms measure approximately 2.0 cm in length; males are slightly smaller at 1.7 cm. Adults of both sexes possess three fleshy anterior "lips" that are characteristic of ascarid nematodes. Conspicuous lateral alae run along the cuticle, which itself is finely striated (Orihel and Ash, 1995).

On histopathologic examination, *L. minor* usually does not present with diagnostic difficulty, taking into consideration epidemiology, anatomic site, and parasite morphology. Adults of *L. minor* possess many of the characteristics inherent to other ascarid nematodes, including coelomyarian/polymyarian musculature and tall, slender uninucleate intestinal cells. Typically, *L. minor* occurs in anatomical sites not parasitized by other ascarid nematodes, with the exception of ectopic anisakiasis. The prominent lateral alae are a key diagnostic feature, especially when seen in conjunction with features of an adult worm, such as ovaries or testes; other ascarid nematodes that present with alae are larval, including L3 larvae of *Ascaris lumbricoides* (lung), *Baylisascaris procyonis* (liver, CNS), and *Toxocara* spp. (liver, lung, CNS) (Orihel and Ash, 1995).

Fig. 2 Cross section of *Lagochilascaris* in a biopsy specimen stained with hematoxylin-and-eosin (H&E), showing prominent lateral alae, coelomyarian/polymyarian musculature, and tall intestinal cells. This figure represents *L. spreuti*, a parasite of the opossum, but the species shares the same morphologic features as *L. minor* in humans. Introduction

Infectious diseases such as brain infection, encephalitis, and meningitis are less common in developing countries, but its outcome always potentially fatal (Sarrazin et al., 2012). Increased understanding of risk factors, clinical features, diagnostic tools, and advancement in microbiology considerably decreased the number of people suffering from these infectious diseases. However, infectious diseases are tenacious and continue to be a significant health concern in low- and middle-income countries (Fonkwo, 2008).

Encephalitis is an acute inflammation of brain parenchyma with relatively severe neurological outcomes (Ellul and Solomon, 2018). Sometimes, acute meningitis can be clinically indistinguishable from acute encephalitis. Worldwide incidence of encephalitis ranges from 1.5 to 7/100,000 inhabitants/year with a fatality of 7% (Boucher et al., 2017). Although *Herpes simplex virus* (HSV) infection is the most common cause of encephalitis (Quist-Paulsen et al., 2013) the bacterial strains such as *Streptococcus pneumoniae*, *S. pyogenes*, *Listeria monocytogenes*, *Mycobacterium tuberculosis*, *Bacillus anthracis*, *Chlamydia trachomatis*, *Leptospira* sp., *Borrelia burgdorferi*, and *Salmonella* sp. also causes encephalitis (Granerod et al., 2010). *L. monocytogenes* may cause meningoencephalitis, a syndrome where features of both meningitis and encephalitis are present. The survivors' from encephalitis often presents residual physical or neuropsychological deficits (Ellul and Solomon, 2018).

Meningitis is an infection caused by pathogens that leads to inflammation of the brain and spinal cord coverings called meninges. In the United States, infection of viral, bacterial, fungi and parasites, and unspecified reasons accounts for the meningitis cases. The higher incidence is still prevalent in the meningitis belt of sub-Saharan Africa, with incidence rates varying between 10 and 40 per 100,000 inhabitants. In contrast, in the United States and Europe, the incidence rate varied between 0.7 and 7.1 per 100,000, which accounts for all causative pathogens (Castelblanco et al., 2014; Figueiredo et al., 2018). Recently published systematic review reports the global frequency of meningitis causing microorganisms in all ages reveals that in America, *N. meningitidis*, *S. pneumoniae*, and *H. influenzae*; in Europe *N. meningitidis*, *S. pneumoniae*, *Staphylococcus aureus*, *S. agalactiae*, *H. influenzae*, and *L. monocytogenes*; in Africa *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, *E. coli*, *S. aureus*, *L. monocytogenes*, and *S. agalactiae* (Oordt-Speets et al., 2018). The bacterial meningitis is either community-acquired or nosocomial (hospital-acquired). It often results from the invasion of the bacteria into the meninges from blood, or it may reach from local infection. The most common bacterial strains that lead to infection vary by age (Table 1). *S. pneumoniae* was the most common cause of bacterial

Table 1 Invasion of CNS pathogen and clinical diseases.

Bacterial pathogen	Age	Sites of entry and colonization	Bacterial adherence and invasion	Entry to CNS	Clinical diseases
<i>Streptococcus pneumoniae</i>	1–3 months 3 months to 3 years 3–10 years	Nasopharynx and lung	Cell wall-anchored proteins, cytolysin, capsule	Invasion across the blood-brain barrier (BBB) and blood cerebrospinal fluid barrier (BCSFB)	Neonatal, pediatric and adult meningitis, brain abscess, and encephalitis (Liu et al., 2010; Pick, 2016)
<i>Streptococcus agalactiae</i>	0–3 months 3 months to 3 years	Hematogenous spread from mother to infant, nasopharynx, intestinal tract	Cell wall-anchored proteins, hemolysin, capsule, LTA, pili	Invasion across the BBB and B-CSFB	Neonatal meningitis and brain abscess (Pick, 2016; Stoner et al., 2015; Dando et al., 2014)
<i>Neisseria meningitidis</i>	1–3 months 10–19 years	Nasopharynx	Capsule, type IV pili, outer membrane proteins (Opa, Opc, FBA, ACP, MspA)	Invasion across the BCSF	Pediatric, infant and adult meningitis (Pick, 2016; Chauhan et al., 2008)
<i>Listeria monocytogenes</i>	0–3 months 3 months to 3 years	Intestinal tract and blood-borne	Internalin, InlI	Invasion across the BBB	Neonatal and adult meningitis, encephalitis and brain abscess (Pick, 2016; Mosa et al., 2009; Popowska et al., 2017)
<i>Haemophilus influenzae</i>	Below 15 year	Nasopharynx	Capsule, Hap, HMW1, HMW2, Hia/Hsf, and hemagglutinating pili	Remains unclear	Meningitis and brain abscess (Galdiero et al., 2001; Kim, 2008; Doran et al., 2016; Rodriguez et al., 2003)
<i>Escherichia coli</i>	1–3 months	Hematogenous spread from mother to infant, nasopharynx, intestinal tract	OmpA, K1 capsule, CNF1, fimbriae, lbeA	Invasion across the BBB	Meningitis, brain abscess, and choroiditis (Pick, 2016; Krishnan et al., 2012)
<i>Mycobacterium tuberculosis</i>	2–4 years	Nasopharynx and blood-borne	ESAT-6, Mpt64 and CFp2	Invasion across the BBB	Meningitis, CNS tuberculosis (Rock et al., 2005; Mezocho et al., 2017; Ramsugit and Pillay, 2016)
<i>Klebsiella pneumoniae</i>	3 months to 50 years	Nasopharynx	Outer membrane protein KpOmpa	Invasion across the BBB	Meningitis (Lee et al., n.d.; Li et al., 2014; Pichavant et al., 2003)
<i>Pseudomonas aeruginosa</i>	3 months to 50 years	Nasopharynx and lung	Outer membrane protein EstA, OprD, OprG and PA3923.	Invasion across the BBB	Meningitis (Gallagher et al., 2017; Bodey et al., 1983; Paulsson et al., 2019)

meningitis (58.0%), *S. agalactiae* (18.1%), *N. meningitidis* (13.9%), *H. influenzae* (6.7%), and *L. monocytogenes* (3.4%). The other strains, such as *E. coli*, *Klebsiella* sp., *Enterobacter* sp., and *Pseudomonas aeruginosa* accounts for less common causes of infection. The bacterial strains, such as *S. pneumoniae*, *S. aureus*, *S. epidermidis*, and some Gram-negative bacilli, account for the hospital-acquired meningitis infection (Chacon-Cruz et al., 2019; Linder and Malani, 2019). Recent studies have put forth evidence that the prevalence of bacterial meningitis has dramatically diminished with the utilization of conjugate vaccines, antimicrobial therapy, and adjuvant treatment in developed countries. However, survivors from meningitis often suffer from neurological sequelae, including hearing loss, focal neurological deficits, and cognitive impairment (Lucas et al., 2016).

Both bacterial meningitis and encephalitis are acute infections which need medical attention promptly to avoid mortality and poor neurological outcome. Several extensive studies in children with bacterial meningitis and encephalitis have been done, but there are no large-scale epidemiologic studies evaluating all causes of meningitis and encephalitis in the pediatric population in the United States. In this chapter, we aimed to summarize the mechanism by which the bacterial pathogen invades the immune-privileged central nervous system (CNS), the response of the immune system toward the bacterial colonization, and long-term neurological complications after this dreadful infection.

Colonization of bacteria to cause encephalitis and meningitis

The route of infection in bacterial invasion generally has the cascade of events involving colonization (nasopharynx, respiratory tract, middle ear, maternal vaginal and intestine), bloodstream dissemination, blood-brain barrier (BBB) and blood-cerebrospinal fluid (BCSF) barriers crossing, and finally entry into the subarachnoid space, survival and subsequent infection (de Steenhuijsen Piters et al., 2015; Dando et al., 2014). In general, the nasal cavity easily exposed to inhaled microbes, allergens, and particulate material. The epithelium lining the nasal nares and the cavity harbor normal bacterial flora, and CNS pathogens, such as *S. aureus*, *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*, may asymptotically colonize in the nasopharynx (Oikawa et al., 2014; Bogaert et al., 2011; Rasmussen et al., 2000). Several events that occur following infection of human nasopharyngeal is associated with mucus independent of capsular polysaccharide, fimbriae, or immunoglobulin A subclass 1 (IgA1) protease production; (i) cytotoxicity characterized by the breakdown of epithelial-cell tight junctions, called ciliostasis; (ii) selective attachment to nonciliated epithelial cells; (iii) multiplication and formation of microcolonies on the epithelial surface; (iv) invasion of the epithelium by intracellular or intercellular routes; and (v) passage of organisms to the submucosa (Tunkel and Scheld, 1993). The details of bacterial pathogen and their route of entry, respective bacterial adhesion protein involved, and their route of entry to CNS is detailed in Table 1.

Maternal vaginal colonization

The first step involves the successful bacterial colonization of the mucosal surface in adherence to luminal epithelial cells and/or surface host proteins. Vaginal pH facilitates the increased bacterial adherence to vaginal epithelial cells and extracellular matrix (ECM) proteins, which has been observed *in vitro* as pH shifts from acidic to neutral (Park et al., 2012). Few surface-expressed determinants such as serine-rich repeat (Srr) proteins, Srr-1 and Srr-2, alpha-like proteins, the pilus protein PilA of the GBS pilus island (PI)-2a, bacterial surface adhesins (Bsa) B, BspA, and immunogenic bacterial adhesin (BibA) have been shown to contribute to vaginal and cervical epithelial cell adherence protein (Santi et al., 2007). Other than these surface-expressed determinants, some bacterial constituents, including β -hemolysin/cytolysin toxin and carotenoid pigment, and MntH, an H^+ -dependent manganese transporter elicits adherence or vaginal persistence to host (Patras and Nizet, 2018).

Nasopharyngeal colonization

The transmission of the pathogen occurs between individuals by coughing and sneezing. The pili identified is most commonly responsible for the initial attachment to the host. The first pilus is an oligomeric appendage encoded by the *rlrA* operon, and the second pilus is encoded by pilus islet 2. To reach and colonize in nasopharynx, the pathogen degrades mucus by exoglycosidases such as neuraminidase A, β -galactosidase, β -N-acetylglucosaminidase, and neuraminidase B, decreasing mucus viscosity and preventing mucus entrapment (Burnaugh et al., 2008). Then they interact with additional adhesins such as phosphorylcholine, which binds to the platelet-activating factor receptor (PAF-R), CbpA (Rosenow et al., 1997). They facilitate transcytosis through the mucosal epithelial cell layer from the apical membrane to the basal membrane (Prager et al., 2017). Binding and crossing the epithelial cell layers allows access to the submucosal layer, leading to invasive illness.

Bacteraemia

The host defense opposes the bacterial entry in the blood include complement-mediated opsonization and phagocytosis. For survival, the pathogen increases its capsule size, reduces complement deposition on its surface, and reduces subsequent interaction with phagocytes (Kadioglu et al., 2008). This is achieved by inhibiting complement-mediated clearance by recruiting factor H that inhibits the complement cascade (Li et al., 2007). Some other defense is recognition of the bacteria by antigen-presenting cells

through the binding of pattern recognition receptor (PRR). These events result in the release of cytokine further induce the recruitment of neutrophils and lymphocytes and simultaneously cause cerebrovascular damage (Prager et al., 2017).

S. pneumoniae is internalized by human and rat BMECs via receptor-mediated endocytosis. This uptake does not involve the formation of cellular membrane protrusion (Ring et al., 1998). Polysaccharide capsule may also be an essential virulence factor for invasive disease caused by *S. pneumoniae*. *S. pneumoniae* induces the translocation of β -arrestin from the cytosol to the plasma membrane, then colocalizes with the platelet-activating factor (PAF) receptor. It stimulates mitogen-activated protein kinases (MAPK) signaling required for pneumococcal uptake. Vacuoles containing *S. pneumoniae* colocalized with endosomal markers; however, increased expression of β -arrestin promotes the transcytosis of viable bacteria. The interactions between PAF receptor and β -arrestin contribute to the transcellular penetration of HBMECs by *S. pneumoniae* (Radin et al., 2005).

N. meningitidis makes initial attachment and colonization in nasopharyngeal mucous membranes in humans. Studies have confirmed that pili are essential mediators of attachment of meningococci to human cells. The receptors for meningococcal pili are found to be more in nasopharyngeal mucous surfaces (Salit and Morton, 1981; Stephens and McGee, 1981). An experimental model of human columnar nasopharyngeal tissue in organ culture demonstrated the interaction of encapsulated, piliated *N. meningitidis* with the mucosal surface. Electron microscopic results showed that meningococci attached selectively to nonciliated columnar cells of the nasopharynx (Stephens et al., 1983). Type IV pili mediate the attachment of *N. meningitidis* to HBMECs. Although the initial attachment is inhibited by cerebral microcirculation once attached, *N. meningitidis* proliferates and able to resist its thorough, strong bacterium-bacterium and bacterium-host interactions (Mairey et al., 2006). Identified CD46 dependent and independent attachment to host cells (Kirchner and Meyer, 2005). Furthermore, studies with human bronchial epithelial cells show that the meningococcal type IV pilus binds to the PAF receptor, and that synergy between a pilin-linked glycan and phosphorylcholine decorating moieties is required for pili to efficiently engage the receptor (Jen et al., 2013).

L. monocytogenes utilize the nasopharyngeal route to enter the CNS. Then the invasion occurs using the Trojan horse mechanism or by transcellular penetration of HBMECs. In human umbilical vein endothelial cells (HUVECs) and HBMECs, it was demonstrated that *L. monocytogenes* could invade endothelial cells directly or via cell-to-cell spread from adherent and infected mononuclear phagocytes in the neonatal period (Drevets et al., 1995). In HUVECs, *L. monocytogenes* attachment induces membrane ruffling that leads to internalization (Parida et al., 1998). In HBMECs, *L. monocytogenes* invasion preceded by intimate interactions between the bacterium and microvilli on the cell surface (Greiffenberg et al., 2000). The invasion of *L. monocytogenes* into HBMECs requires actin microfilaments; however, the activation of phosphatidylinositol 3-kinase has not involved (Greiffenberg et al., 1998).

E. coli proteins contribute to the adhesion to and invasion of HBMECs; the virulence factors promote the destruction of tight junctions between BMECs. In addition to triggering the internalization of *E. coli* K1 into HBMECs, the binding of outer membrane protein A (OmpA) to its gp96 homolog receptor stimulates inducible nitric oxide synthase and nitric oxide production, which enhances the generation of cyclic GMP (Krishnan et al., 2012; Mittal and Prasadarao, 2010). This increase in cyclic GMP activates protein kinase C (Sukumaran and Prasadarao, 2003).

Central nervous system bacterial invasions cause brain infection, encephalitis, and meningitis

The BBB is a dynamic and complex system that separates the brain from the blood. It prevents neurotoxic plasma components, blood cells, and pathogens from entering the CNS (Sweeney et al., 2019). The BBB composed of endothelial cells, and it is regulated by pericytes, microglia, astrocytes, and neurons. BBB's specialized endothelial cells contain in their membranes, tight junctions by occludin, claudins, and junctional adhesion molecules and water channels that have altogether guard the transport of polar substances and infectious organisms (Cereijido et al., 1998). The traversal of the BBB by the pathogen is a prerequisite for all types of brain infections. The pathogen successfully crosses the BBB by transcellular, paracellular, and infected phagocytes (Trojan-horse) mechanism to infect the host. Microbial traversal through barrier cells occurs (i) With no trace of microorganism and no evidence of tight-junction disruption called transcellular traversal; (ii) With or without tight-junction disruption called paracellular traversal; and (iii) Using transmigration within infected phagocytes called the Trojan-horse mechanism (Kim, 2006, 2008).

The bacterial pathogen such as *E. coli*, *S. agalactiae*, *S. pneumoniae*, and *N. meningitidis* utilize transcellular traversal to penetrate the BBB. The bacterial pathogen, such as *L. monocytogenes* and *M. tuberculosis*, penetrate the BBB through both transcellular and Trojan-horse mechanism.

Pathogen ligand-receptor interaction

S. pneumoniae crosses the BBB partly through interactions between cell-wall phosphorylcholine and the PAF-receptor. It was demonstrated by the PAF-receptor antagonist, which partially inhibited the pneumococcal invasion of HBMECs (Ring et al., 1998). In PAF-receptor knockout mice, it delayed the translocation of *S. pneumoniae* from the lung to blood and blood to cerebrospinal fluid (CSF) (Cundell et al., 1995).

N. meningitidis interacts with endothelial and epithelial cells, and this interaction involves type IV pili, PilC, *N. meningitidis* adhesin A (NadA), and the Opa and Opc (outer membrane) proteins. The unencapsulated *N. meningitidis* invade the HBMECs by Opc binding to fibronectin, which anchors the bacteria to the integrin $\alpha 5 \beta 1$ receptor on the surface of HBMEC (Unkmeir et al., 2002). However, it is unclear, the encapsulated *N. meningitidis* and the in vivo relevance of Opc-fibronectin-mediated binding. *N. meningitidis* type IV pili bind to CD46 on HBMECs, and their LPS has been shown to contribute to a high level of bacteremia and penetration into the CNS (Plant et al., 2006).

L. monocytogenes invasion into CNS is mediated by internalin B (Greiffenberg et al., 1998). The HBMEC receptors for internalin B, includes gC1q-R (globular head of the component C1q-receptor) and Met tyrosine kinase but their contributions to *L. monocytogenes* invasion of HBMECs is little known (Braun et al., 2000). The internalin B does not compete for the same interaction site on Met as the natural ligand hepatocyte growth factor (Braun et al., 2000). The CNS penetration attributed to the transmigration of *L. monocytogenes*-infected monocytes and myeloid cells across the BBB (Drevets et al., 2004). However, further studies are needed to determine the major route of *L. monocytogenes* penetration into the CNS.

The neonatal meningitis pathogens *S. agalactiae* accommodates a number of proteins that allow binding and invasion of HBMECs. *S. agalactiae* binds to HBMECs through laminin-binding protein (Lmb), the fibrinogen-binding protein (FbsA), pili, and invasion-associated gene A (IagA) occurs through LTA anchoring (Tenenbaum et al., 2007; Doran et al., 2005; Maisey et al., 2007). Still, it is not clear that the above proteins are unique to *S. agalactiae* CSF isolates and its role in contributing to penetration into the CNS (Kim, 2008).

E. coli binding to HBMECs is contributed by the determinants, Type 1 fimbriae and OmpA (Teng et al., 2005; Khan et al., 2003). It has also been shown that the amino-terminal region and surface-exposed loops of OmpA contribute to binding to HBMECs (Shin et al., 2005) and that OmpA interacts with HBMECs through N-acetylglucosamine residues in HBMEC glycoproteins, including gp96 (Prasadarao et al., 2003; Khan et al., 2003). A recent study used an *E. coli* DNA microarray to compare an OmpA mutant with its parental *E. coli* K1 strain and revealed that the OmpA mutant expressed significantly fewer film cluster genes (Teng et al., 2006). Other *E. coli* determinants that contribute to invasion of HBMECs include recombinant Ibe proteins (Huang et al., 2001). It was supported as the polyclonal antibody raised against IbeA inhibited *E. coli* K1 invasion of HBMECs (Prasadarao et al., 1999). Besides, CNF1 contributes to *E. coli* K1 invasion of HBMECs in vitro and traversal of the BBB in vivo that depends on RhoA activation (Khan et al., 2002).

M. tuberculosis penetrates the BBB through a transcellular traversal or Trojan-horse mechanism. A study showed that strains of *M. tuberculosis* invade and traverse HBMECs; the invasion was significantly increased for the *M. tuberculosis* strains (H37RV and CDC 1551) than for the non-pathogenic strains (Jain et al., 2006). Using DNA microarray analysis 33 upregulated genes and 147 downregulated genes in *M. tuberculosis* that was associated with HBMECs compared with *M. tuberculosis* that was not associated with HBMECs. Mutants of five *M. tuberculosis* genes were attenuated for their ability to invade and/or survive in the brain (Be et al., 2008).

H. influenzae penetrates between epithelial cells via an unknown mechanism. Interaction with PAF receptor demonstrated in *H. influenzae* serotype b (Weiser et al., 1998), but the role of the PAF receptor in *H. influenzae* penetration into the CNS is not clear. Intracisternal inoculation *S. pneumoniae* diminished the pleocytosis by PAF-receptor antagonist but had no effect on the pleocytosis induced by *H. influenzae* (Cabellos et al., 1992). Zyxin is a vital protein protecting the tight junction of the BBB against cell transmigration across the BBB. Notably, tumor necrosis factor (TNF) α mediated decrease in zyxin significantly increased the migration of the *H. influenzae* (Miyazaki et al., 2014). In an experimental model using macaques, the earliest histopathologic lesions were observed on choroid plexus after *H. influenzae* infection (Smith, 1987). *H. influenzae* isolated from CSF after intranasal inoculation was associated with intravascular inflammatory infiltration and mild choroid plexitis (Daum et al., 1978). As explained above, the pathogenic bacteria utilize different transport mechanisms to penetrate the BBB to reach the brain (Fig. 1).

Recognition of bacterial infection by innate immune sensors

The general function of innate and adaptive immunity allows the host to detect pathogen entry and to initiate an inflammatory response to clear the invaders, thereby prevents host homeostasis. However, during the fight against the invaders, the CNS with lower regenerative profile, damage to host tissues is more prominent (van der Flier et al., 2003).

When the pathogen reaches the subarachnoid space, the bacteria multiply and establishes its colony, which further releases the cell wall fragments, lipopolysaccharide (LPS), lipoteichoic acid (LTA), teichoic acid, pneumolysin, and peptidoglycan (Mook-Kanamori et al., 2011). All these compounds are immunogenic and elicit an inflammatory response to the host. The concept of pattern recognition receptors (PRRs), a sensor for the innate immune system, is essential to understand the innate immune response. This non-clonal receptor can recognize structures common to many pathogenic organisms, known as pathogen-associated molecular patterns (PAMPs) (Janeway, 2001). Recognition of PAMPs occurs through toll-like receptors (TLRs), RLRs (retinoic acid-inducible gene-1-like receptor), cytosolic DNA sensors, and Nod-like receptors (NLRs). However, RIG-I-like receptors (RLRs) are a family of cytosolic PRR that is essential for detecting viral RNA (Kawai and Akira, 2009; Hanke and Kielian, 2011).

Toll-like receptors (TLRs)

Studies have identified a family of membrane-bound TLRs (TLR1-TLR10) 10 in humans and (TLR1-TLR9, TLR11, and TLR13) 12 in mice (Kawasaki and Kawai, 2014). TLRs expressed in dendritic cells (DCs), macrophages, fibroblasts, and epithelial cells. TLRs generally serve as PRRs to recognize a wide range of PAMPs, including lipids, lipoproteins, proteins, glycans, and nucleic acids, either on the cell surface or on the lumen of intracellular vesicles such as endosomes (Kawai and Akira, 2009). The cell surface TLRs include TLR1, TLR2, TLR4, TLR5, TLR6, and TLR10; the intracellular TLRs include TLR3, TLR7, TLR8, TLR9, TLR11, TLR12, and TLR13 (Kawai and Akira, 2010). TLR2 recognizes triacyl lipopeptides from bacteria and mycobacteria, diacyl lipopeptides from mycoplasma, peptidoglycan, and LTA from Gram-positive bacteria, porin from *Neisseria*, lipoarabinomannan from mycobacteria (Hoebe et al., 2005). TLR4 activates pneumolysin, and TLR9 activates pneumococcal DNA containing CpG motifs within

Fig. 1 Mechanisms of bacterial recognition and BBB disruption that facilitates bacterial-host interactions upon bacterial infection. NOD1 and NOD2 cytosolic receptors specifically recognize peptidoglycans present within the bacterial cell wall *Escherichia coli*, *Listeria monocytogenes*, *Mycobacterium tuberculosis*, and *P. aeruginosa*. *Staphylococcus aureus*, *E. coli*, *L. monocytogenes*, and *Klebsiella activates* NLRP3 through bacterial toxins. Lipopolysaccharide from Gram-negative bacteria recognized through TLR4 transmembrane protein. Invasion of the pathogen to the central nervous system achieved by specific protein present on the blood-brain barrier or blood-cerebrospinal fluid barrier.

endosomes. TLR4 activated by LPS, a principal constituent of the outer membrane of Gram-negative bacteria. It enables the adaptor protein (AP), myeloid differentiation primary response gene 88 (MyD88)-dependent pathway, and the TIR-containing adapter inducing interferon (IFN) β (TRIF)-dependent pathway (Akira et al., 2006; Hanke and Kielian, 2011). TLR5 recognizes *Listeria* sp. through its flagellin (Hayashi et al., 2001).

MyD88-dependent pathway

The MyD88 acts as a canonical adaptor for inflammatory signaling pathways downstream of members of the TLR and interleukin (IL)1 receptor families (Gay and Keith, 1991). It links the IL1 receptor (IL1R) or TLR family members to IL1R-associated kinase (IRAK) family kinases (Deguine and Barton, 2014). TLR engagement induces the formation of the Myddosome, which is based on MyD88 and also contains IRAK1 and IRAK4. IRAK1 activation also induces TNF-receptor (TNFR)-associated factor (TRAF) 6 activation following K63-linked polyubiquitination on TRAF6 itself and transforming growth factor- β -activated kinase (TAK)1. TAK1 activation leads to the activation of I κ B kinase (IKK) complex nuclear factor kappa B (NF κ B) and MAPK. Thus, IRAK family kinases activation leads to a variety of functional outputs, including the activation of NF κ B, MAPKs (Chen, 2012; Ajibade et al., 2013). MAPK activation further activates AP1 transcription factor activation. During bacterial infection, TRAF6 translocated to mitochondria, where it interacts with evolutionarily conserved signaling intermediate in Toll pathway (ECSIT) and results in increased mitochondrial and cellular reactive oxygen species (ROS) generation. Interestingly, studies demonstrated that deficiency of MyD88, adapter protein in children, increases their susceptibility to invasive pneumococcal meningitis (von Bernuth et al., 2008). In a preclinical model, MyD88-deficient mice have demonstrated a lack of responsiveness to LPS, the ligand for TLR4. Though MyD88 deficiency protected the mice from endotoxic shock, MyD88-deficient cells retained some residual signaling when stimulated with LPS, suggesting MyD88-independent signaling mechanisms downstream of TLR4 (Kawai et al., 1999). TLR7 is predominantly expressed in plasmacytoid DCs and recognizes RNA from streptococcus B bacteria (Kawasaki and Kawai, 2014). The details on signaling pathways triggered by Toll-like receptor (TLR) and Nod-like receptor (NLR) are given in Fig. 2.

TRIF-dependent pathway

TRIF-related adapter molecule (TRAM)—TRIF (TLR4 signaling) induce inflammatory responses via the recruitment of TRAF6, a member of the TRAF family of proteins. TRAF6 recruits the receptor-interacting protein (RIP)-1, which in turn interacts and activates the TAK1 complex, leading to activation of NF κ B, MAPKs, and induction of inflammatory cytokines. On the other hand, TRAF3 recruits the IKK-related kinases TANK-binding kinase (TBK)1 and IKKi (epsilon; IKK ϵ) along with NF κ B essential modulator (NEMO) for IRF3 phosphorylation. Subsequently, IRF3 forms a dimer and translocates into the nucleus from the cytoplasm, where it induces the expression of type I IFN genes (Akira et al., 2006; Kawai and Akira, 2010).

A well-recognized function of Peli family members—E3 ubiquitin ligases is participation in the signal transduction mediated by TLRs and IL1 receptors (Jin et al., 2012). Pellino-1-deficient mice display impaired TRIF-dependent NF κ B activation and cytokine production (Chang et al., 2009). TBK1/IKKi phosphorylates Pellino-1 that facilitates the ubiquitination of RIP-1; further, recruitment of RIP-1 is essential for TRIF-dependent NF κ B activation. Furthermore, Pellino-1 regulates IRF3 activation by binding to deformed epidermal autoregulatory factor (DEAF)-1, a transcription factor that facilitates the binding of IRF3 to the IFN- β promoter. Recently, IRF3 activation was demonstrated to be regulated by an inositol lipid, phosphatidylinositol 5-phosphate (PtdIns5P). PtdIns5P binds to both IRF3 and TBK1, and thus facilitates complex formation between TBK1 and IRF3. The accessibility of TBK1 to IRF3 mediated by PtdIns5P causes IRF3 phosphorylation (Fig. 2; Kawasaki et al., 2013).

Nod-like receptors (NLRs)

In the cytosol, the NLR (NOD-like receptor) family detects the presence of PAMPs and endogenous molecules. NLRs consist of three domains characterized by an N-terminal protein interaction domain, a central nucleotide-binding domain, and a C-terminal leucine-rich repeat (LRR). Members of the NLR family categorized into at least five subfamilies distinguished by their N-terminal structures (Meylan et al., 2006; Fritz et al., 2006; Kanneganti et al., 2007). The ligands of nucleotide-binding oligomerization domain-containing protein (NOD)1 and NOD2 categorized as NLRC1 and NLRC2, respectively, and are well-characterized members of the NLR family that recognize distinct structural motifs derived from peptidoglycan. NOD1 recognize pathogenic bacteria such as *E. coli*, *Shigella flexneri*, *P. aeruginosa*, and *Chlamydia* species intracellularly. NOD2 participates in sensing *Streptococcus pneumoniae* and *M. tuberculosis* (Kanneganti et al., 2007). *L. monocytogenes* activates both NOD1 and NOD2. Signaling via NOD1 and NOD2 results in the induction of inflammatory cytokines and other anti-microbial genes, thereby contributes to host defense mechanisms (Kobayashi et al., 2005). *H. influenzae* commonly found in the upper respiratory tract classified encapsulated or nonencapsulated form. Encapsulated serotype B is the most virulent one of the leading causes of meningitis young children. NOD1 is implicated in the intracellular recognition of this enteroinvasive pathogenic bacterial *H. influenzae* (Kanneganti et al., 2007).

Cytosolic DNA sensors

Cytosolic DNA sensors can also detect bacterial pathogens. For example, cyclic GMP-AMP (cGAMP) synthase (cGAS) recognizes a variety of intracellular bacteria, including *L. monocytogenes* (Hansen et al., 2014) in macrophages and activates absent in melanoma (AIM) 2 inflammasomes (Tan et al., n.d.). This recognition also occurs in the cytoplasm of many cell types, including immune and non-immune cells, and it triggers a type I IFN response via TBK1 that phosphorylates the transcription factor IRF3 (Stetson and Medzhitov, 2006).

Fig. 2 Signaling pathways triggered by Toll-like receptor (TLR) and Nod-like receptor (NLR). The TLR complex recruits a TIR domain-containing adaptor complex, including TRAM—MyD88 and TRIF adaptors. MyD88 pathway: MyD88 recruits IRAK family members and TRAF6 to activate TAK1. The TAK1 complex activates the IKK complex composed of IKK α , IKK β , and NEMO (IKK γ), which catalyze the phosphorylation of I κ B proteins. Phosphorylated I κ B proteins are degraded, allowing NF- κ B to translocate to the nucleus. TAK1 simultaneously activates the MAPK pathway. The activation of NF- κ B and MAPK results in the induction of inflammatory cytokine genes. TRIF pathway: TRAM-TRIF recruits TRAF6 for activation of TAK1 as well as TRAF3 for activation of TBK1-IkKi that phosphorylates and activates IRF3. Whereas NF- κ B and MAPK regulate expression of inflammatory cytokine genes in both pathways, IRF3 regulates expression of type I IFN in the TRIF-dependent pathway only. NOD-like receptor: The ligands NOD1 is NLRC1, and NOD2 is NLRC2; they recognize distinct structural motifs derived from peptidoglycan.

NLRP-3 inflammasome

The NLRs respond to many PAMPs from pathogens and lead to the release of the IL1 family of inflammatory cytokines, including IL1 β , IL18, and IL33, through the formation of the NLRP-3-inflammasome, which involves caspase-1 apoptotic pathway (Meylan et al., 2006; Yu and Finlay, 2008; Fritz et al., 2006). Upon activation, NLRP3 oligomerizes with apoptosis-associated speck-like protein containing a CARD (ASC) and pro-caspase 1. Procaspase-1 is converted to activated caspase-1, which subsequently matures and secretes the pro-inflammatory cytokines IL1 β and IL18 in their mature form caspase-1 mediates the processing of the pro-form of these cytokines into mature forms, which results in the secretion of bioactive cytokines. The stimuli such as bacterial toxins, β -hemolysin, pneumolysin, listeriolysin O, and bacterial compounds activate the inflammasome. *Pneumococcus* pneumolysin

exotoxin activates NLRP3 and AIM2 100 and β -hemolysin. *S. agalactiae* invasion activates NLRP3. NLRP3 also has been associated with the responses to several microorganisms, such as *S. aureus*, *L. monocytogenes*, *K. pneumoniae*, and *E. coli* (Davis et al., 2011). Infection by *Listeria* sp. sensed by AIM2 and NLRC4, which activates NLRP3 and leads to strong caspase1 activation and pro-inflammatory response (Wu et al., 2010).

Central nervous system immune response to bacterial infection

Microglia

Microglia are one of the major resident mononuclear phagocytes that participate in innate immune responses in CNS. Microglia act as a baseline immune sentinel that defense against invading pathogens into the CNS before peripheral leukocyte infiltration (Norris and Kipnis, 2019). When bacterial pathogen crosses the BBB, microglia responds either directly to the bacteria or the cell wall antigens. In response to cell wall components, microglia produces inflammatory mediators such as IL6, TNF α , IL12, keratinocyte-derived chemokine (CXCL1/KC), CCL2/MCP1, CCL3/MIP1 β , CXCL2/MIP2, and CCL5/RANTES, as well as soluble TNF receptor II, TNF α antagonist (Rock et al., 2004; Hanisch, 2002). The inflammatory mediators' production involved activation of the extracellular signal-regulated protein kinases ERK1 and ERK2 via a MAPK intracellular signaling pathway (Hanisch, 2002). To elicit antibacterial defense, this microglial-derived cytokine profile is effective at leukocyte recruitment into the CNS. Along with the complement pathway, microbial activation leads to post-infection cognitive impairment by the loss of hippocampal synapses (Vasek et al., 2016). In dogs with meningoencephalitis, the marked levels of Th1, Th2, and Th17 related cytokine, CXCR3, CCR2 chemokine receptor mRNA, microglia/macrophage levels were reported (Park et al., 2013). We recently demonstrated the in vivo microglial activation after *S. pneumoniae* induced meningitis in the rat model using [^{11}C]PBR28-PET imaging (Giridharan et al., 2020). Besides, several studies have reported the microglial activation after *S. pneumoniae* infection (Djukic et al., 2006). In the animal model, neuro-invasive infection by *L. monocytogenes* demonstrated activation of microglia (Zhang et al., 2018). A study by Hoogland et al., reported that systemic challenge with live *E. coli* induces microglial activation 3 days after inoculation, at the same time no production of pro-inflammatory cytokines in the brain was found. In CNS tuberculosis patients monocyte, *M. tuberculosis* upregulates microglial matrix metalloproteinase 1 and 3 expressions and secretion via NF κ B and activator protein 1 dependent monocyte networks (Green et al., 2010). Challenge of infant rats' brains with *H. influenzae* type b intraperitoneally resulted in the time-dependent expression of MIP2, MIP1 α , MCP1, and RANTES, the expression of RANTES was localized predominantly to resident microglia (Diab et al., 1999).

Astrocytes

The astrocytes are macroglial resident cells of the CNS, play critical roles in and elimination of neurotoxins, and invading bacterial pathogen by the production of trophic factors. Astrocytes orchestrate with microglial cells to regulate the recruitment and activity of infiltrating hematogenous cells through their expression of cytokines, proteases, protease inhibitors, adhesion molecules, and extracellular matrix components (Mucke and Eddleston, 1993). In addition to its role in the immune system, the functions of astrocytes include the maintenance of BBB. Glial fibrillary acidic protein (GFAP) is an astrocyte-specific protein belonging to the intermediate filament protein at grade III, whose increased level is strongly correlated with brain development. The level of GFAP has been shown to exhibit elevations in cases of bacterial meningitis, highlighting the leakage of the BBB.

Pneumolysin a major *S. pneumoniae* neurotoxin as a factor in remodeling the structure of the host brain tissue by astrocyte reshaping and interstitial fluid retention, thereby increases the penetration of toxic macromolecules and bacteria into the tissue and worsens the disease course (Hupp et al., 2012). In murine astrocyte cultures, *S. pneumoniae* upregulates the macrophage receptor with collagenous structure (MARCO), that mediates the production of IL1 β in astrocytes (Braun et al., 2011). Astrocytes recognize *L. monocytogenes* infection uses TLR2 and NOD1 PRR system during neonatal and adult meningitis (Mosa et al., 2009). Intracerebral injection of *E. coli* K1 E44 strain into mice induced expression of the astrocyte differentiation marker glial fibrillary acidic protein and the inflammatory mediators' cyclooxygenase 2 and nitric oxide synthase 2 (Wu et al., 2009). Challenge of infant rats' brains with *H. influenzae* type b intraperitoneally resulted in the time-dependent expression of MIP2, MIP1 α , MCP1, and RANTES, the expression of RANTES was localized predominantly to resident microglia (Diab et al., 1999).

Future studies dissecting the potential roles of inflammatory mediators and their receptors in the context of CNS infectious diseases may provide insights into the complex regulatory network inflammatory responses.

Glymphatic system

The CNS was believed to be devoid of a lymphatic system. The identification of the *glymphatic* pathway in rodent brain changed this scenario (Baciyinski et al., 2017). This pathway subserves, the flow of CSF to the perivascular spaces, penetrating arteries of the brain, mixes with interstitial fluid (ISF) and solutes in the parenchyma and then exits along with the perivascular spaces of draining veins which are facilitated by aquaporin 4 (AQP4) water channels (Rasmussen et al., 2018). It gained importance when it was identified as a pivotal contributor to the clearance of interstitial solutes from the brain, including amyloid β , a major misfolded protein in Alzheimer's disease. Hence recently, attention raised to increase the knowledge of glymphatic dysfunction, which might provide a new perspective for understanding the pathophysiology of brain infection.

Cytokines

Release of the inflammatory mediator cytokine is a one of a significant event that occurs after bacterial invasion. As underactivation of cytokine results in an inadequate immune response, whereas overactivation can be extremely destructive. Proinflammatory cytokines such as TNF α , IL1, IL6, and IL8 and the anti-inflammatory cytokines IL10 and TGF β are involved in the pathophysiology of the bacterial pathogen. The cerebrospinal fluid neonates with bacterial meningitis presented with high levels of TNF α , IL1 β , and IL6 (Krebs et al., 2005; Fida et al., 2006). In children with bacterial meningitis, exhibited an increase in TNF α , IL6, and IL8 concentrations in the CSF (Prasad et al., 2014). The results from meta-analysis reported that the TNF α and IL1 β levels were identified as useful markers for the prediction of bacterial meningitis (Panato et al., 2014). IL6 is produced in response to infections and tissue injuries. It contributes to the host immune defense through the stimulation of acute-phase proteins, fever, leukocytosis, and the activation of the complement cascade (Tanaka et al., 2014). The concentration of IL6 in patients with acute bacterial meningitis CSF (Vazquez et al., 2012; Takahashi et al., 2014), and the serum were significantly elevated (Hamed et al., 2012). Elevated levels of IL6 in the CSF of pediatric patients with bacterial meningitis observed with no association of bacteremia, neurologic complications, or sequelae (Rusconi et al., 1991). In experimental meningitis, IL6 deficient mice presented an increase in the inflammatory response in the CSF; however, there was also a reduction of vascular permeability, intracranial pressure, and BBB disruption during the bacterial meningitis infection (Paul et al., 2003). In experimental models, IL6 has shown a dual role as both a pro-inflammatory and anti-inflammatory cytokine (Paul et al., 2003; Cohen and Cohen, 1996).

The cytokines play the significant role as an inflammatory mediator after encephalitis infection. The CSF concentration of IL6, IFN γ , IL10, and sTNFR1 was significantly higher in encephalitis patients (Ichiyama et al., 2008). IL5 is expressed intrathecally in encephalitis act as a mediator and marker (Grygorczuk et al., 2016, 2018a,b). In a mice model of encephalitis resistant C57BL/6 mice protected against encephalitis independently of signaling via TNFR1 or TNFR2 (Lundberg et al., 2007). The IL12 is chemotactic and activates natural killer (NK) cells, and induces their binding to endothelial cells CD4 T cells preferentially differentiate toward Th1 cells in the presence of IL12. Besides, these cell types, neurons have IL12 receptors exogenous IL12 treatment results in host recovery from encephalitis. IL12 administration to mice results in rapid clearance of the pathogen, increased survival, and enhanced recovery from infection (Ireland et al., 1999). Understanding the levels of cytokines is a crucial intervention is one of the possible strategies. The intervention of inflammatory response at the cytokine level can be achieved by different avenues (i) inhibition of transcription of the cytokine gene; (ii) blockage of the cytokine itself; (iii) by cleavage to activate the procytokine; and iv. antagonism of the cytokine receptor and its downstream signaling pathways (van der Flier et al., 2003).

Chemokines

Chemokines are the other inflammatory mediators released after bacterial entry. They are produced at sites of inflammation at the luminal side of endothelial cells or on the surface of the heparan sulfates (Middleton et al., 1997). The CSF of patients with bacterial meningitis contains detectable levels of the C-X-C chemokines (IL8) and C-C chemokines (monocyte chemotactic protein 1 [MCP1], macrophage inflammatory proteins MIP1 α and MIP1 β) (Spanaus et al., 1997). In experimental models of meningitis, neutralization of C-X-C had a sustained effect, and neutralization of MCP1 reduced macrophage infiltration, whereas systemic neutralization of MIP1 α or MIP2 with antibody temporarily reduced neutrophil influx into the CSF. However, intrathecal neutralization of IL8 did not affect immune cell recruitment (Diab et al., 1999; Ostergaard et al., 2000). In encephalitis, CSF-CXCL1 concentrations correlated with neutrophil count was higher in patients with encephalitis (Grygorczuk et al., 2016, 2018a,b). The CSF concentration of CCL5 was increased in encephalitis, the highest in the most severe presentation (Grygorczuk et al., 2006, 2016, 2018a,b).

Complement system

Infection by bacterial pathogen strongly activates the complement system of plasma proteins (Jack et al., 1998; Jarvis and Griffiss, 1989). The major pathways by which complement may be activated after bacterial colonization is through the antibody-mediated classical pathway (C1q, C1r, C1s, C4 and C2); direct binding of complement components to the pathogen surface called alternative pathway (Factor B and Factor D); and the mannose (or mannan) binding lectin (MBL) pathway (Lewis and Ram, 2014). MBL, as the name suggests, can recognize and bind to mannose on pathogen surfaces. Notably, individuals who are deficient in complement proteins have an increased risk of meningococcal disease (Walport, 2001). In particular, the interaction of molecules of the complement system with the bacterial pathogen has proven important in disease pathogenesis as it establishes a significant contribution to the development of newer vaccine formulations.

Clinical consequences and post-mortem findings of brain infection, encephalitis, and meningitis

Brain infection, such as meningitis and encephalitis, is highly fatal without treatment. Even with treatment, fatality is 5–10% within two days of symptom development, and more than 10% of the survivors are left with severe sequelae (Meningococcal meningitis fact sheet #141, 2018). The most common neurological disabilities in children surviving meningitis infection are sensorineural hearing impairment, seizures, academic and behavioral difficulties, and a decrease in intelligence (Saez-Llorens and McCracken, 2003) while in adults hearing loss and cognitive impairment are the most common neurological complications (van de Beek et al., 2006).

Growing evidence also confirms the increased risk of psychiatric and behavioral problems such as post-traumatic stress disorder, attention deficit hyperactivity disorder, separation anxiety, depression as well as schizophrenia and psychotic symptoms in the life of children surviving meningitis (Abraham et al., 2005; Khandaker et al., 2015; Olbrich et al., 2018). Khandaker et al. demonstrated that children with a childhood meningitis history showed poor performance on all neurocognitive and academic measures, showed increased depression, anxiety symptoms, psychological and behavioral issues, and showed a twofold increase in the risk of psychotic experiences in the long-term compared to healthy controls (Khandaker et al., 2015). Hence, it is very crucial to acknowledge and try to minimize these severe sequelae in survivors.

The most common complications during meningitis infection, mainly caused by pneumococcus, were cerebrovascular diseases (van de Beek et al., 2006; Weisfelt et al., 2006b). Around 30% of the patients suffered from an arterial stroke, and around 9% suffered from cerebral venous thrombosis, while intracranial hemorrhages were seen in approximately 9% of patients (Kastenbauer and Pfister, 2003; Weisfelt et al., 1996, 2006a). Inflammatory infiltrates seen in cerebral arteries and veins in various post-mortem studies (Buchan and Alvord, 1969; Cairns and Russell, 1946; Dodge and Swartz, 1965), which along with the segmental arterial narrowing seen on angiography, leads to the hypothesis that vasculitis could be the underlying pathophysiological mechanism of infarction seen in bacterial meningitis patients. Delayed cerebral thrombosis (DCT), which is a rare but devastating complication seen in 2–4% cases of pneumococcal meningitis, causes multiple cerebral infarcts (Lucas et al., 2013; Schut et al., 2009). An autopsy study comparing the histopathology of brain samples from pneumococcal meningitis patients with DCT and without DCT with non-meningitis controls reported that several factors could cause DCT, such as inflammation of vessels, thromboembolism of large arteries and infectious intracranial aneurysms (Engelen-Lee et al., 2018). Pneumococcal capsule components were also reported to be present in the meninges for a long-duration after meningitis and might be responsible for the increase in inflammation after the initial immunosuppression by dexamethasone wears off ultimately leading to DCT and cerebral infarcts (Engelen-Lee et al., 2018). Another post-mortem study demonstrated that fibrin thrombi and brain infarcts were frequently present in the brain samples of pneumococcal meningitis patients. At the same time, inflammatory vessel wall infiltrates were absent, suggesting that diffuse cerebral intravascular coagulation can be another etiologic factor causing ischemic stroke in pneumococcal meningitis (Vergouwen et al., 2010).

Apart from infarction, other mechanisms of neuronal damage have also been reported by several post-mortem studies. Apoptotic neuronal damage in the dentate gyrus of hippocampal formation has been reported in autopsy samples from bacterial meningitis patients, which might explain the learning deficits frequently seen in the survivors of bacterial meningitis (Nau et al., 1999). Though the exact mechanism of apoptosis of neurons in bacterial meningitis is not known, free radicals and excitatory amino acids may be responsible for it. A substantial contribution of axonal pathology to neuronal damage in bacterial meningitis was also demonstrated in another post-mortem study. Extensive axonal injury caused predominantly by ischemia was reported to be present in the white matter of human and animal post-mortem brain samples (Nau et al., 2004).

Similarly, the selective synaptic loss was also seen in the frontal neocortex in autopsy samples from pneumococcal meningitis patients. In this study, pneumolysin is hypothesized to play a synaptotoxic and dendritotoxic role in pneumococcal meningitis by releasing glutamate from astrocytes and ultimately causing excitotoxic synaptic damage (Wippel et al., 2013). In conclusion, various mechanisms causing neuronal damage should be further explored to find new therapeutic targets for decreasing the frequency of debilitating neuropsychiatric sequelae in survivors of meningitis.

Conclusion

The recognition of immune privilege to CNS is attributed to its various tissue properties such as the presence of physical barriers, the absence of traditional lymphatics, and the lack of major histocompatibility complex class II expressing antigen-presenting cells. Classically, immune privilege in the CNS is a double-edged sword. Although it makes the neuroprotective mechanism, in the context of CNS infections, and immune privilege not considered beneficial to the host. In this chapter, we summarized the bacterial invasion, the central immune response to the invaded bacteria, and its long-term neurological sequelae after meningitis and encephalitis. It is crucial to understand the interactions between the complex immune network, inflammatory profile, and bacterial virulence factors as it may aid in developing potential therapeutic strategies for these infectious diseases.

Introduction

Several viruses exhibit tropism for the central nervous system and/or peripheral nervous system. The majority are RNA viruses (Tables 1 and 2). Viral infection in the nervous system can result in a multitude of clinical presentations, including acute or chronic meningitis, encephalitis, myelitis, polyradiculitis, and peripheral neuropathy.

Viruses can directly affect the nervous system, such as in meningitis and encephalitis, or indirectly (parainfectious or post-infectious) from inflammatory or immunologic reactions, such as in Guillain-Barré syndrome (GBS) or acute disseminated encephalomyelitis (ADEM) (Barah et al., 2014; Helgeson et al., 2018; de Almeida et al., 2007; Steiner et al., 2005).

Clinical aspects

All segments of the nervous system, central or peripheral, can be involved in viral infections. Neurological complications of RNA and DNA virus are summarized in Tables 1 and 2. Concerning the central nervous system, the main clinical presentations are meningitis and encephalitis.

Meningitis is the most common infectious CNS syndrome, defined as an inflammation of the meninges. Viruses can cause acute or chronic meningitis. The clinical symptoms of acute meningitis are fever, malaise, and vomiting, and in some cases, petechial rashes. Signs of meningeal irritation include neck stiffness, Kernig's sign (an inflection of the knee when the limb is placed at a certain degree of relative inflection to the trunk), and Brudzinski's sign (an involuntary inflection of the limb following a head inflection). These signs are poorly sensitive in adults; both Kernig and Brudzinski signs have a sensitivity of only 5%, while the sensitivity of nuchal rigidity is 30%. The nonspecific nature of the symptoms and clinical signs means that we often overtreat and require additional exams to confirm a diagnosis (Thomas et al., 2002). Signs of meningeal irritation are rare among younger children. Instead, small children can present other signs, such as an inability to feed, vomiting, drowsiness, convulsions, and a bulging fontanel.

Encephalitis includes clinical signs of brain parenchyma, involving fever, chronic headache, and conscience alteration, which can be followed by focal neurological signals or seizures of recent onset. Meningoencephalitis occurs when meningitis is followed by involvement of the brain parenchyma (de Almeida et al., 2007).

The spinal cord can be affected by virus infection in any of its segments. The clinical presentation of acute viral myelitis can be divided into poliomyelitis-like gray matter syndrome, or partial or complete white matter syndrome. First, pure motor deficit occurs, which consists of weakness and one or more flaccid limbs without sensory deficit or urinary bladder. Then, prominent sensory disturbances, urinary retention, and weakness with either hypo- or hyperreflexia with myelitis occur, due to the involvement of the white matter. This involvement usually affects only part of the transverse expanse of the spinal cord and manifests as asymmetric motor and sensory symptoms. In acute transverse myelitis, both halves of the spinal cord are affected (Kincaid and Lipton, 2006).

Monticelli et al., 2018; Thompson and Thakur, 2017; Barah et al., 2014.

Cognitive impairment is present in several CNS virus infections, mainly in chronic infections, such as HIV or HCV, or as sequelae of acute encephalitis, as HSV-1 encephalitis (Tables 1 and 2).

Acute meningitis

Viral meningitis is a global disease that can be either sporadic or epidemic. The main cause of acute viral meningitis are non-polio enteroviruses, with around 80–95% of the cases, especially during the summer months. The remaining cases are caused by several other virus (Tables 1 and 2) (de Almeida et al., 2007; Vidal et al., 2011, 2019). Despite its low mortality rates, viral meningitis can be associated with a high morbidity. Coxsackie virus sub-group B is responsible for 60% of cases of meningitis among children under 3 years of age. Enterovirus 70 and 71 show strong neurotropism, which is associated with meningoencephalitis, polio-like paralytic syndromes, GBS, or meningitis (Teoh et al., 2015).

The viruses of the herpes family are collectively responsible for 4% of meningitis cases. Meningitis is more frequently caused by HSV-2, while HSV-1, and EBV are associated with recurrent lymphocytic meningitis (de Almeida et al., 2007). Parotid disease can be associated with meningitis in 10–20% of cases. It is more frequent during winter months, and it occurs in males in a 3/1 ratio (Rhie et al., 2016).

Encephalitis

Herpes simplex, mainly HSV-1, is the most common cause of sporadic encephalitis, while arboviruses being the most common overall, mainly during epidemic. Human herpes virus 6 is an emerging cause of encephalitis in immunocompetent and immunodeficient patients.

Neuroimaging findings, such as edema and necrosis in one of the temporal lobes, are strongly indicative of herpetic encephalitis.

Arboviruses

Arbovirus (arthropod-borne virus) causes emergent and re-emergent viruses. Outbreaks of these viruses have become more frequent due to increases in climatic change, deforestation, and urbanization (Carod-Artal et al., 2013; Tournabize et al., 2009). Several arboviruses are restricted to specific geographical areas, and can thus be considered traveler diseases (Thompson and Thakur, 2017; Petersen et al., 2016). Arboviruses encompass viruses of distinct genera or families, which are transmitted by arthropod vectors. They comprise a group of over 100 RNA neurotropic and neurovirulent viruses, which mainly cause encephalitis but also meningitis. Some examples include Flavivirus: dengue, yellow fever virus, Saint Louis encephalitis virus, Powassan virus, Japanese encephalitis virus (JEV), West Nile virus (WNV), Murray Valley Encephalitis virus, Tickborne Encephalitis virus, Louping III virus, Kyasanur Forest Disease virus, Rocio virus, Ilheus virus, and Zika virus. Alphavirus: Chikungunya virus, equine encephalitis virus (Eastern (EEE), Western (WEE), Venezuelan (VEE)), Semliki Forest virus, Me Tri virus, Mayaro; Bunyavirus: California (La Crosse), Oropouche, Phlebovirus: Rift Valley Fever virus, Toscana virus; Reoviridae: Colorado tick fever; Rhabdoviridae: Chandipura virus (Weaver and Reisen, 2010; Solomon et al., 2000; Solomon, 2004; Figueiredo, 2007; Fragoso et al., 2016; Liu and Chambers, 2001; Qureshi et al., 2012; Simon et al., 2016; Wang et al., 2020; Muñoz et al., 2016; Soares et al., 2020).

Hepatitis viruses

Hepatitis viruses encompass a range of diverse and unrelated groups of viruses from different families, with the common characteristics of hepatotropism, hepatovirulence, and hepatotoxicity. The hepatitis viruses of neurological interest primarily comprise RNA viruses, hepatitis A, C, and E viruses (HAV, HCV, and HEV, respectively), and a DNA virus, hepatitis B virus (HBV) (Sellner and Steiner, 2014). Viral hepatitis can be accompanied by various extrahepatic manifestations in both acute and chronic infections.

HCV and HBV are the most frequent hepatitis viruses with nervous system involvement (Yimam et al., 2013), although it has also been described with HAV and HEV, albeit with a lower frequency (Ferro et al., 2016).

Hepatitis viruses can affect the entire nervous system, including the brain, spinal cord, motor neurons, peripheral nerves, and muscles. The most common neurological manifestations of HCV and HBV are peripheral neuropathy.

Hepatitis C virus

The extrahepatic manifestations of HCV are independent of the severity of the underlying chronic liver disease and hepatic encephalopathy. Neurological complications of HCV occur mainly in chronic infections, but can also occur in acute cases. Nervous system impairment occurs in more than 50% of chronically infected HCV individuals (Iriana et al., 2017). HCV mainly affects

neurons responsible for motor function, memory, and concentration (Monaco et al., 2015). Although the incidence of HCV infection is lower than that of HBV, chronicity occurs in up to 85% of cases (Sellner and Steiner, 2014); this could explain the higher frequency of neurological complications.

Nervous system complications in patients with HCV include peripheral neuropathy, which is the most common neurological complication among subjects with chronic HCV infection (Adinolfi et al., 2015). HCV infection is known to cause motor, sensory, and sensorimotor mononeuropathy, mononeuropathy multiplex, or polyneuropathy (Adinolfi et al., 2015). Symptomatic peripheral neuropathy was observed in 9% of cases (Cacoub et al., 2000). In contrast to the brain, there is currently no evidence for HCV replication in peripheral nerves (Adinolfi et al., 2015). Peripheral neuropathy associated with HCV is usually associated with cryoglobulinemia, which is mainly characterized by axonal damage. It was postulated that nerve damage is secondary to epineural vessel changes caused by occlusion or vasculitis induced by longstanding cryoglobulin precipitation with complement fixation and rheumatoid factor (RF) deposition. Vasculitis or vascular occlusion causes fascicular ischemia, leading to axonal degeneration (Nemni et al., 2003). GBS associated with HCV infection is rare. The mechanism of GBS is based on the autoimmune-induced demyelination of peripheral nerves, which often occurs after an infectious episode. Chronic inflammatory demyelinating polyneuropathy associated with HCV has also been described (Ferro et al., 2016).

A significant proportion of patients with chronic HCV experience cognitive impairment and HCV neurocognitive disorders in the absence of advanced liver disease, which may interfere with their daily living activities and quality of life (de Almeida et al., 2018). The rates of cognitive impairment vary widely across studies (0–82%), reflecting differences in co-morbidities and experimental methods (Huckans et al., 2009). Several studies have investigated domain-specific cognitive impairments in HCV-positive patients and found deficits in attention, concentration, working memory, executive function, and psychomotor speed (Perry et al., 2008; de Almeida et al., 2018). Cognitive impairment was not found to be correlated with HCV RNA in the peripheral blood or cerebrospinal fluid (CSF) or the presence of cirrhosis (Clifford et al., 2015; de Almeida et al., 2018), and was not dependent on the HCV subtype (Monaco et al., 2015; de Almeida et al., 2018).

Human immunodeficiency virus

Neurological complications of human immunodeficiency virus (HIV) infection are summarized on Table 3.

Acute meningitis is present in 5–10% of HIV-infected patients, usually before seroconversion, as well as during or after the observation of mononucleosis-like signs and symptoms. Its clinical evolution is self-limited. It can be asymptomatic or accompanied by focal neurological signs, such as peripheral facial palsy. The CSF has a biochemical and cellular pattern compatible with that of acute viral meningitis (Heaton et al., 2010). Anti-HIV enzyme-linked immunosorbent assays (ELISA) often yield negative results with blood and CSF samples. Patients at risk of HIV infection are advised to have a second serological diagnosis test for HIV after 4–6 weeks. However, no specific biomarker in the CSF or blood helps diagnose acute meningitis caused by HIV. The p24 antigen test for the early diagnosis of HIV using blood samples is neither sensitive nor standardized for CSF analysis.

Chronic meningitis is present in 40% of infected individuals at any stage of HIV infection, while 59% are asymptomatic. Because it is an exclusion diagnosis, other causes of chronic meningitis must be ruled out (de Almeida et al., 2008). CSF presents with pleocytosis (5–50 cells/mm³) and increased total protein level (50–100 mg/dL), while glucose, the CSF blood glucose ratio, and lactic acid are in the normal range (Fishman, 1992; Zink and Clements, 2000; de Almeida et al., 2011a).

HIV associated neurocognitive disorder (HAND) is the main neurological complication directly associated with HIV infection, and is a clinical diagnosis (Heaton et al., 2010; Antinori et al., 2007; de Almeida et al., 2013). CSF analysis is important for ruling out opportunistic infections and co-infections. Several biomarkers in CSF with the potential to diagnose HAND have been studied. However, they are not clinically applicable (Brew and Letendre, 2008; de Almeida et al., 2005; Cinque et al., 2007; Gisslen et al., 2007; Hagberg et al., 2010) and are only used in research. With the aging of the HIV population, other biomarkers have become important and have been investigated (Brew et al., 2005; Gisslén et al., 2009; Krut et al., 2013; Krut et al., 2014). The same can be

Table 3 Neurological complications of HIV infection.

Vacuolar myelopathy			Hepatitis C virus
Parkinsonism			Chagas disease
			Malaria
			Schistosomiasis
			NPCM

HAND, HIV-associated neurocognitive disorder; *IRIS*, immune reconstitution inflammatory syndrome (after starting antiretroviral); *NPCM*, neuroparacoccidioidomycosis; *PML*, progressive multifocal leukoencephalopathy.

applied to polyneuropathies and myelopathy associated with HIV. HIV vacuolar myelopathy occurs in 10% of patients with AIDS; it is an exclusion diagnosis. Other frequent causes of myelopathy, such as neurosyphilis, HTLV, CMV, and specific endemic etiologies, must be ruled out.

Neurons do not have a CD4 receptor, the main receptor involved in HIV cell invasion. Consequently, HIV does not infect neurons. Neuronal injury in HIV infection results from an indirect mechanism due to the complex interaction of anions, inflammatory and neuronal injury proteins, and constitutional HIV proteins. These proteins have been investigated as biomarkers in the CSF or serum for CNS HIV infection. It is possible that pyroptosis plays an important role in neuronal lesion and death. Pyroptosis markers in the CSF of patients infected with HIV have not yet been studied. The mechanism of cell death, namely, apoptosis, which can be described as the death of cells with a productive infection caused by HIV, does not depend on the inflammatory process. Rather, it is associated with the activation of caspase-3. Recently, a mechanism of cell death in HIV-infected cells, called pyroptosis, was described. The term pyroptosis refers to proinflammatory programmed cell death, a form of cell death that lies between apoptosis and necrosis. Pyroptosis is dependent on caspase-1, which in turn depends on inflammatory processes. Caspase-1 is not involved in apoptotic cell death, and caspase-1-deficient cells respond normally to most apoptotic signals. The HIV-1-induced death of CD4 T lymphocytes is mediated by pyroptosis. The two mechanisms of programmed cell death, apoptosis and pyroptosis, are not exclusive (Doitsh et al., 2014a; Doitsh et al., 2014b; Monroe et al., 2014).

IRIS-HIV is characterized by the occurrence of opportunistic infections or non-infectious inflammatory disease within weeks of initiating or changing ARV treatment, despite improvements in immunological status. Approximately 15–25% of patients who receive ARV treatment develop IRIS HIV within the first few months of therapy. The nervous system is a frequent target. Biomarkers in the CSF that diagnose IRIS have yet to be identified, and the diagnosis is based on clinical criteria (Lipman and Breen, 2006; Venkataramana et al., 2006).

The CNS acts as an important reservoir for HIV (Karris and Smith, 2011; Zárate et al., 2007; Haggerty and Stevenson, 1991). Several constitutional characteristics specific to the CNS support the view that the CNS is an immunologically privileged site. HIV can infect two types of cells in the CNS: cells derived from monocytes (microglia and macrophages) and astrocytes. Specific CNS immunological characteristics, the blood-brain barrier (BBB), rapid mutation and recombination of HIV, and poor ARV penetration in the CNS contribute to the compartmentalization of HIV in the CNS. Some organs, such as the CNS, genital tract, and gastrointestinal lymphoid tissue, are viral compartments and reservoirs that allow HIV to persist despite ARV therapy, which eliminates the virus from the peripheral blood. Compartments are defined as anatomical regions that restrict the genetic flow of HIV, thereby enabling viral evolution and divergence from the virus circulating in the peripheral blood. On the other hand, reservoirs are cells or anatomical sites where HIV or HIV-infected cells survive because the viral kinetics are slower than those in the peripheral blood. Compartments and reservoirs protect HIV from specific immune responses, ARV therapy, and biochemical changes, thereby providing an environment for the pathogen to freely interact with its host (Karris and Smith, 2011; North et al., 2010).

In treatments with a combination of ARV drugs, the main objective is to suppress HIV replication in all cells and tissues (Dore et al., 1999). The effective treatment of HAND most likely entails the complete suppression of HIV replication in the CNS. The incomplete suppression of the virus in the CNS, caused by factors such as lack of ARV penetration in the CNS, can promote viral mutations and resistance to ARV drugs, both of which allow the virus to redistribute to non-CNS tissues. In this context, the CNS is considered a possible reservoir or sanctuary for HIV (Abbott, 1987).

HIV exhibits high genetic and antigenic variability. Mutation and recombination are the main mechanisms underlying the genetic diversity of HIV and the evolution of the HIV-1 pandemic (Thomson and Nájera, 2005; Nájera et al., 2002). The high genetic diversity of HIV can be attributed to the lack of a control mechanism for reverse transcriptase activity and the consequent high error rate (0.2–2 mutations per genome per cycle), in association with a high replication rate, accompanied by rapid viral turnover (Korber et al., 2001; Domingo, 1998).

The failure of some ARV drugs to penetrate the CNS contributes to persistent neurocognitive deficits and allows for slow replication in the CNS. Improvements in neurocognitive performance after 12 weeks of HAART is greater in those who receive ARV drugs with better CNS penetration (Ariën et al., 2007). Despite the limited CNS penetration of most ARV drugs, HAART is partially effective in suppressing HIV replication in the CNS. Although some HAART-based treatments are better than others with regard to CNS penetration (Langford et al., 2006), ARV drugs must be selected to prevent viral activity in the CNS, limit neuron dysfunction, and prevent or treat HIV-infected patients with HAND. In addition, these strategies may help prevent the development of ARV resistance (Letendre et al., 2010).

Despite the effective suppression of viremia with ARV therapy, HIV can still replicate in the CNS, with the development of resistant strains in the CNS in patients with acute and sub-acute neurological manifestations (Zárate et al., 2007; Haggerty and Stevenson, 1991; Harrington et al., 2009). Discordance between the HIV viral loads in the plasma and CSF is defined by an HIV RNA viral load in the CSF that is ≥ 1 log higher than that in the plasma. CNS escape is defined as any detectable value of CSF HIV RNA while plasma HIV RNA is undetectable (Canestri et al., 2010).

Coronaviruses

Coronaviruses (CoVs) are enveloped viruses with a positive-sense single-stranded RNA genome that belong to the Coronaviridae family and the Nidovirales order. CoVs are classified into four genera: alpha, beta, gamma, and delta. Alpha, beta, and delta

coronaviruses infect mammals, whereas delta and gamma coronaviruses infect avian species (Li, 2016). However, CoV has the ability to jump between species, leading to the emergence of severe respiratory syndromes in humans, such as severe acute respiratory syndrome (SARS) caused by SARS-CoV-1, Middle East respiratory syndrome (MERS) caused by MERS-CoV, and COVID-19 caused by SARS-CoV-2 (Li, 2016). The neurotropic, neuro-invasive, and neurovirulent capabilities of CoV have been described in animals and humans, leading to encephalitis, meningitis, or encephalomyelitis. However, the capacity of CoV to infect the CNS in humans is not well characterized (Bohmwald et al., 2018). Both SARS-CoV and MERS-CoV have been proven to be neurotropic and neurovirulent (Tsai et al., 2005; Saad et al., 2014); however, nervous system complications are more frequent with SARS-CoV2 (Alshebri et al., 2020; Almqvist et al., 2020). Encephalitis and meningitis have been reported in SARS-CoV, MERS-CoV, and SARS-CoV2 (Alshebri et al., 2020).

The SARS-CoV-2 virus was first described in Wuhan, China in December 2019. In a few months, it spread to nearly every country in the world, with large economic, social, and health impacts, and a great number of deaths (Thompson, 2020). In addition to systemic and respiratory symptoms, 36.4% of patients with SARS-CoV-2 infection develop neurological symptoms (Mao et al., 2020).

Neurological parainfectious complications of SARS-CoV-2 infection include anosmia, myalgia, meningitis, encephalitis, stroke, and metabolic encephalopathy. Viral encephalitis caused by SARS-CoV-2 was described in Beijing, China, with the presence of the virus confirmed in CSF (Xiang et al., 2020; Favas et al., 2020). Post-infectious complications include ADEM, acute necrotizing hemorrhagic encephalopathy, transverse myelitis, GBS, and sensory neuropathy (Atakla et al., 2020). The post-infectious complications of SARS-CoV-2 are of inflammatory and immunological origin. In some cases, encephalopathy has been reported to present symptoms or manifestations of SARS-CoV-2 infection (Poyiadji et al., 2020; Alshebri et al., 2020).

The interval of 5–10 days between the onset of viral illness and the first symptoms of GBS is similar to that seen with that which occurs during or after other infections (Wijdicks and Klein, 2017; Kim et al., 2017; Sharma et al., 2019; Toscano et al., 2020).

Cognitive impairment is being considered as a manifestation of SARS-CoV-2 infection, with severely affected COVID-19 cases experiencing high levels of proinflammatory cytokines and acute respiratory dysfunction. All these factors have been suggested to cause cognitive decline. Pathogenetically, this may result from the direct negative effects of the immune reaction, the acceleration or aggravation of pre-existing cognitive deficits, or the de novo induction of neurodegenerative disease (Heneka et al., 2020; Fernandez-Gonzalo et al., 2020).

Ischemic stroke was described in SARS-CoV, MERS-CoV, and SARS-CoV2. The mechanism likely involves endothelial dysfunction, immune-mediated injury leading to cytokine storm and coagulation abnormalities, and hypoxia-induced injury (Alshebri et al., 2020). The majority of reported stroke cases in the literature were related to SARS-CoV2 infection, most of which had an elevated D-dimer level (Alshebri et al., 2020).

Brain autopsies in COVID-19 showed chronic neurological disease and acute abnormalities; low levels of viral SARS-CoV-2 RNA were present; however, the cellular source remains unknown. Acute hypoxic injury, hemorrhage, and minimal inflammation were frequently observed (Mukerji and Solomon, 2021).

John Cunningham virus (JCV)

JCV is a polyomavirus, a DNA virus. Seroepidemiological studies have indicated that asymptomatic primary infection with JCV occurs in childhood before 5 years of age, and that, by adult life, roughly 85% of the population is seropositive. Following primary infection, JCV becomes latent in sites including the kidney, bone marrow, and tonsils. By contrast, it is unclear whether CNS latency occurs. JCV reactivation in immunocompetent hosts usually takes the form of asymptomatic viruria (Tan and Koralnik, 2010).

Progressive multifocal leukoencephalopathy (PML), a subacute demyelinating disease of the CNS, is a result of the infection of oligodendrocytes by JCV (Koralnik, 2006). In the context of impaired cell-mediated immunity, including immunosuppressive drug treatment, lymphoproliferative disorders, chronic infectious or inflammatory diseases, such as tuberculosis and sarcoidosis, AIDS, and treatment with immunomodulatory biologicals, JCV can reactivate to produce PML (Clifford et al., 2010; Major, 2010; Tan and Koralnik, 2010).

Laboratory investigation

The diagnostic investigation of virus infection is performed by nucleic acid amplification tests (NAAT) in cerebrospinal fluid (CSF). The diagnostic characteristics of NAAT vary between viruses. Multiplex assays include several viruses, which cause nervous system infections. Despite its high sensitivity, polymerase chain reaction (PCR) can still provide false-negative results. Pre-analytical care is crucial to obtain the best results. CSF samples must be collected on DNase and RNase tubes to avoid destroying viral genetic material, and transported on ice to the laboratory. This is particularly important for RNA viruses, which are less stable. The presence of hemoglobin in body fluid samples has been considered an important inhibitory factor for PCR. Other factors include the quality of samples submitted to the lab, small recovery rates of genetic material from the sample during processing, low specificity of primers, optimization of reagents, failure to use nuclease-free materials, or the presence of a series of PCR inhibitory factors in the samples. Various body fluids, such as saliva, urine, serum, stool, amniotic fluid, and cerebrospinal fluid (CSF), contain intrinsic agents that can inhibit PCR (Davies et al., 2005; Ochert et al., 1994; Spreer, 2015; de Almeida et al., 2016). Other clinical samples, such as feces, urine, and blood, can be analyzed in association with the CSF; however, a positive reaction does not confirm CNS infection.

Currently, the study of viral agents is performed using molecular biology methods, where real-time polymerase chain reaction (qPCR) is the most suitable method. The positivity of molecular biology methods depends on a series of factors, such as sample quality; thus, samples must always be transported on ice and collected in suitable tubes. The time between the onset of symptoms and sample collection is also important (Davies et al., 2005).

The polymerase chain reaction (PCR) in the CSF, which amplifies the HSV DNA, is the method of choice for HSV diagnosis (Al-Shekhlee et al., 2006; Anderson et al., 1993). The PCR results were positive 24–48 h after the beginning of neurological symptoms and remained positive for 2–5 days after the beginning of treatment with antivirals. The sensitivity of the PCR reaction depends on a series of factors. The sensitivity of PCR for HSV is 94%, with a specificity of 98%, a positive predictive value of 95%, and a negative predictive value of 98% (Tyler, 2004; Lakeman et al., 1995).

There is a relationship between the detection of the virus by PCR in the CSF and the onset of neurological symptoms. The highest positivity of the PCR for enterovirus occurs between the 3rd and 14th day (Davies et al., 2005).

HIV RNA in the CSF

HIV particles present in the CSF can have different origins: they can drain from perivascular spaces or infected cells of the meninges, or they can originate in the plasma and pass through the choroid plexus during CSF production, particularly in the case of damage to or inflammation of the choroid plexus (Zink and Clements, 2000). In clinical practice, determining the HIV viral load in the CSF is important for monitoring the therapeutic effects of ARV treatment, identifying patients with CNS escape (compartmentalization), and for determining the differential diagnosis in psychiatric disorders (Tyler and McArthur, 2002).

The correlation between HAND and HIV viral load in the CSF is dependent on the degree of immunosuppression. In cases with a CD4 count of >200 cells/mm³ the HIV viral load in the CSF correlates positively with that in the peripheral blood, but not with HAND. After the initiation of ART, the HIV viral load in the CSF and blood decreases. In patients with a CD4 count <200 cells/mm³, the HIV viral load in CSF correlates positively with cognitive symptoms, but not with the viral load in the peripheral blood. The initiation of ARV treatment leads to a decrease in the CSF viral load, although the decrease is slower than the decrease in the blood (Ellis et al., 1997, 2002; Langford et al., 2006).

Opportunistic infections and co-infections increase the HIV viral load in the peripheral blood. Some opportunistic infections or co-infections in the CNS can increase the viral load in the CSF, as noted in patients with neurosyphilis (de Almeida et al., 2010).

SARS-CoV-2 identification in the CSF

Concerning SARS-CoV-2 identification in CSF, the majority of cases have been undetectable (Espíndola et al., 2020; Lewis et al., 2021), most likely due to a low CSF viral load. The molecular biology tests available are not validated for CSF. A negative RT-qPCR for SARS-CoV-2 in the CSF does not rule out CNS SARS-CoV-2 infection. The diagnosis of SARS-CoV-2 in the CNS is based on cases with neurological symptoms, which fulfill the World Health Organization (WHO) clinical diagnostic criteria for SARS-CoV-2 infection. Cases positive for SARS-CoV-2 by RT-qPCR on nasopharyngeal samples and probable cases negative for SARS-CoV-2 by RT-qPCR on nasopharyngeal samples both presented the clinical and radiological criteria for SARS-CoV-2 infection (WHO, 2020).

Herpes encephalitis

CSF is altered in 97% of cases of herpes encephalitis. However, there are no pathognomonic alterations. There is an increase in CSF white blood cells (WBC) of 5–500 cells/mm³, with a predominance of lymphocytes, moderate CSF total protein increase, and a normal or slightly reduced glucose (Steiner et al., 2005). The presence of red blood cells in the absence of traumatic lumbar puncture occurs in 40% of cases, while xanthochromic CSF occurs in 11% of cases. These two CSF characteristics help to distinguish the diagnosis from other types of encephalitis (Fishman, 1992). Increased IgG levels occurs after the second week of illness. Specific levels of CSF anti-HSV IgG are elevated, corresponding to increased levels in the serum, which can remain high for 3 months to 3 years after acute illness (Kapur et al., 1994). Most patients with HSV have previously developed serum antibodies; therefore, serological tests do not have a diagnostic value. A fourfold increase in serum antibodies does not represent sensitivity or specificity. Intrathecal anti-HSV antibody synthesis occurs, with an increase of four times. Although the relationship between anti-HSV antibodies in the CSF serum has diagnostic value, this increase occurs slowly and is used for diagnostic confirmation retrospectively (Whitley et al., 1982). The detection of specific antibody anti-HSV can be calculated using the relation (antibodies index (AI)) between the CSF serum quotients for the specific antibodies (Q spec) and the IgG quotient (Q IgG), $AI = Q \text{ spec}/Q \text{ IgG}$. Values greater than 1.5 indicate that specific antibodies are synthesized locally (Reiber and Lange, 1991).

New methods

Current data suggest that over one-third of cases of encephalitis remain unidentified, even in the best-equipped medical centers (Granerod and Crowcroft, 2007; Glaser et al., 2006; Venkatesan et al., 2013). Other methods have been developed, such as syndromic panel-based testing (Tansarli and Chapin, 2020) and next-generation sequencing (NGS) methods (Brown et al., 2018).

Diagnosis of lymphocytic meningitis

CSF examination is essential to establish the diagnosis of meningitis and to identify the etiological agent. It is not possible to perform a differential diagnosis between acute viral or bacterial meningitis only on a clinical basis. The CSF characteristics of viral meningitis include an increase in white blood cells (>5 cells/mm³) in the CSF, normal levels of glucose, and normal or increased values of total protein. The CSF lactate levels were within the normal range (<3.5 mmol/L) (Fishman, 1992). Sometimes, the differential is difficult to calculate due to overlapping of CSF characteristics. The predominance of polymorphonuclear (PMN) cells (50%) can occur within the first 6 h of the onset of viral meningitis. After this time, there is a change in the characteristics of the CSF to the typical pattern of viral meningitis. A predominance of lymphocytes can be observed in cases of acute bacterial meningitis in young children, neonates, older patients, immunosuppressed individuals with atypical bacteria, and partially treated cases (Fishman, 1992).

The best test to differentiate bacterial from viral meningitis is the CSF lactate test (Sakushima et al., 2011). CSF lactate concentrations greater than 3.5 mmol/L are characteristic of acute bacterial meningitis. The increase in lactate levels is closely related to low glucose levels (de Almeida et al., 2009). Unlike glucose, the lactate concentration in the CSF is independent of that of the serum. Therefore, there is no need to collect matched serum samples. The CSF lactate levels are also useful for the diagnosis of post-surgical acute bacterial meningitis, when there is no specific increase in cells or proteins (de Almeida et al., 2020).

Other biochemical biomarkers quantified in the CSF that can assist in the differential diagnosis of acute meningitis are shown in Fig. 1 (de Almeida et al., 2011b; Gnutzmann et al., 2016; Kleine et al., 2003).

Fig. 1 Cerebrospinal fluid biomarkers for differential diagnosis of acute bacterial (B) and viral (V) acute meningitis, glucose (mg/dL), lactate (mmol/L), lactate dehydrogenase (LDH, U/L) and C-reactive protein (PCR, mg/dL) (de Almeida et al., 2011b).

Introduction

Fungal central nervous system (CNS) infection is a cause of mortality and neurological morbidity globally. The highest incidence occurs in low-income countries, followed by middle-income and high-income countries (Robertson et al., 2018; Kumar et al., 2020). Global estimates demonstrate that more than 1.5 million people die due to fungal infection, and more than 1 billion people are affected by a fungal infection (Bongomin et al., 2017). In the Leading International Fungal Education (LIFE) platform, the incidence of acquired immunodeficiency syndrome (AIDS)-related cryptococcal meningitis estimated 278,250 cases each year. The global number of disseminated histoplasmosis cases in AIDS worldwide is estimated to be 100,000 annually. Over 30 million can be contaminated with *Aspergillus* sp. each year because of corticosteroid or other therapies, and over 300,000 patients develop infection aggressively annually. Also, candidemia causes ~350,000 cases worldwide every year (Bongomin et al., 2017; Infection, 2020; George et al., 2020).

The fungal brain infection occurs as a consequence of the host immune system impairment, and other health conditions, including the use of medications, chemotherapy, corticosteroid therapies, broad-spectrum antimicrobial, surgical procedures, infection, AIDS, stroke, organ transplantation, end stage renal disease (ESRD) on hemodialysis (HD), neutropenia, and pre-term babies (Bongomin et al., 2017; McCarthy et al., 2014). The respiratory tract is the main route of fungal colonization and infection, followed by hematogenous dissemination and subsequent reaching the CNS. Besides, there are other direct inoculation routes in the CNS, including surgery, trauma, and intravenous drug use. The fungus can also colonize structures underlying the CNS, including sinuses, mastoids, and orbits (Guida, 1988; McCarthy et al., 2014; George et al., 2020).

The most common yeasts that cause brain infection are *Cryptococcus* sp., *Candida* sp., and *Trichosporon* spp. (Guida, 1988). The moniliaceous molds common pathogens are *Aspergillus* sp., *Fusarium* sp., and *Scedosporium* sp. (McCarthy et al., 2014). The Mucoromycetes CNS infections are uncommon, but the most common include the *Mucor* spp. and *Rhizopus* spp. The dimorphic fungi include the *Blastomyces dermatitidis*, *Coccidioides* spp., and *Histoplasma capsulatum*, and dematiaceous fungi *Cladophialophora bantiana* and *Exophiala dermatitidis* (McCarthy et al., 2014; Guida, 1988). In this article, we focus on fungal brain infection. We also explain the mechanisms of fungal invasion, the CNS immune response to the fungal invasion, and its long-term clinical consequences.

Routes of colonization, mechanisms of pathogenesis of fungi to reach the brain

Fungal infections of the CNS follow colonization and dissemination routes, and the respiratory tract is the main route of entry. After the fungi spread via hematogenously, cross the blood-brain barrier (BBB) and subsequently reach the CNS. Also, colonization and infection can occur in structures close to the CNS, including sinuses, mastoids, and orbits. The direct colonization in the CNS occurs after surgery, trauma, and intravenous drug use (McCarthy et al., 2014; Guida, 1988).

The yeasts: *Candida* sp., *Cryptococcus* sp., and *Trichosporon* spp.

Candida genus is a group of Ascomycetes yeast-like fungi that comprises over 30 different species that cause candidiasis, and most of them are rarely isolated from patients. *C. albicans* utilizes different mechanisms of pathogenicity to invade the host cells. *C. albicans* transits between morphological forms of yeast and hyphae. Presents adhesins and invasins on the cell surface, form biofilms, secretes hydrolytic enzymes, adapts to fluctuations of pH, acquires essential nutrients from the host, and protects itself against reactive oxygen species (ROS). The *Candida* sp. can induce cell endocytosis through specialized proteins invasins agglutinin-like sequence 3 (Als3) and Ssa1 on the cell surface that binds to E-cadherin and N-cadherin endothelial cells. Also, the secreted aspartic proteases (Saps) contribute to its active penetration (Mayer et al., 2013). *C. albicans* Als3 invasin binds to the gp96 heat shock protein on the brain endothelial cells' surface and crosses the BBB (Liu et al., 2011).

C. neoformans and *C. gattii* are agents of cryptococcosis disease. However, researchers recognized genetic diversity and the informal nomenclature of *C. neoformans* species complex and *C. gattii* species complex. The species complex demonstrates that two or more cryptococcal species are present in one species name (Hagen et al., 2017; Kwon-Chung et al., 2017). *Cryptococcus* sp. can be inhaled and spread into the host's lungs and disseminate to the bloodstream. *Cryptococcus* sp. crosses the BBB directly by transcytosis through the endothelial cells or using a Trojan-horse strategy that involves transport in phagocytic cells (Kronstad et al., 2011). The capsule is composed of glucuronoxylomannan (GXM) and galactoxylomannan (GalXM) polysaccharides, and these polysaccharides have immunomodulatory properties, and mutants without capsules are avirulent. Cryptococcal cells are resistant to ROS and nitrosative stress (NS) through neutralizing enzymes and protective proteins and metabolites, including superoxide dismutase, flavohemoglobin denitrosylase, glutathione peroxidase, glutathione reductase, thiol peroxidases, thioredoxins, and trehalose (Kronstad et al., 2011). The *Cryptococcus* sp. also uses the lipid signaling pathway diacylglycerol to activates the transcription factor 2 (Atf2) to upregulate expression of the antiphagocytic protein anti-phagocytic protein 1 (App1) (Rhome and Del Poeta, 2010). In summary, the mechanism of pathogenesis includes thermotolerance, resistance to ROS and NS, gluconeogenesis, acetyl-CoA, and melanin synthesis, capsule, and resistance of phagocytosis (Rhome and Del Poeta, 2010; Kronstad et al., 2011).

Trichosporon asahii, *T. asteroides*, and *T. mucoides* are responsible for the trichosporonosis cases in patients undergoing chemotherapy, patients who developed severe and prolonged neutropenia, and those exposed to invasive medical procedures (Colombo et al., 2011; Duarte-Oliveira et al., 2017). The fungus presents galactosaminogalactan (GAG), a virulence factor required to produce biofilms. GAG inhibits neutrophil infiltration and promotes fungal colonization. Also, GAG is an immunosuppressive polysaccharide and facilitates fungal survival (Fontaine et al., 2011; Lee et al., 2016). The *Trichosporon* sp. produces many enzymes, including lipases that hydrolysis triglycerides, phospholipases that hydrolyze phospholipids present in cell membranes, proteases that catalyze proteolysis, and DNases (Bentubo and Gompertz, 2014; Duarte-Oliveira et al., 2017). The fungus is disseminated hematologically and could cross the BBB by a transcellular or paracellular mechanism and colonize the brain.

The moniliaceous molds: *Aspergillus* sp., *Fusarium* sp., and *Scedosporium* sp.

Patients that present a risk factor for aspergillosis include systemic or paraspinal glucocorticoid treatments, neutropenia, mastoidectomy, tuberculosis, asthma, and cancer (Antinori et al., 2013; Ruhnke et al., 2007). After inhalation occurs, the contiguous dissemination spreads to the CNS from the orbits, periorbital regions, middle ear, or paranasal sinuses. The fungus also spreads through the bloodstream into the CNS (Dagenais and Keller, 2009). *Aspergillus* spp. produces aflatoxins and gliotoxins; these mycotoxins inhibit phagocytosis and reduce conidial opsonization. The gliotoxin inhibits assembly of the human cell respiratory burst NADPH oxidase (Yoshida et al., 2000), suppresses the human cellular immune response mediating cell apoptosis (Stanzani et al., 2005), induces a collapse of the actin cytoskeleton around the nucleus leading to cell shrinkage (Coméra et al., 2007). The gliotoxin penetrates and impairs the BBB decreasing the transendothelial electrical resistance (TEER) and increasing permeability, facilitating the fungus invasion into the CNS (Patel et al., 2018; Miceli, 2019).

Fusariosis, an invasive fungal infection caused by *Fusarium* spp., is listed as the second most common opportunistic mold infection after aspergillosis. The *Fusarium* sp. routes of invasion include lungs, sinuses, vascular catheters, and paronychia in neutropenic patients (Antinori et al., 2013). *Fusarium* sp. produces mycotoxins, including deoxynivalenol, 3-acetyldeoxynivalenol, and moniliformin. Deoxynivalenol reduces cell viability, increases BBB permeability, and reduces the expression of claudins facilitating brain infection (Behrens et al., 2015).

CNS infections secondary to *Pseudallescheria boydii* or its anamorph *Scedosporium apiospermum* occur after the aspiration of a large inoculum of the fungi into the lungs (e.g., near drowning in fresh water), which reaches the bloodstream and spreads into the brain. Other routes of infection include orbital infection, neurosurgical procedures or ventriculoperitoneal shunting, and sphenoidal sinusitis (Kowacs et al., 2004). The CNS infection occurs in immunocompetent patients by direct inoculation through neurosurgery, shunts, cerebrospinal fluid (CSF) drainage devices, etc. (Miceli, 2019). The fungus presents a glycoconjugate, peptidorhamnomannan, on the conidia and hyphal cell. The peptidorhamnomannan is associated with fungal adhesion and endocytosis by immune cells facilitating its colonization, virulence, and dissemination in the host (Ramirez-Garcia et al., 2018).

The Mucoromycetes: *Mucor* spp. and *Rhizopus* spp.

Mucoromycetes are the most aggressive mold brain infection, and the risk factor for the development of mucormycosis includes uncontrolled diabetes mellitus, iron-overload conditions, neutropenia or patients receiving glucocorticoid therapy (Ramírez-García et al., 2018; Ibrahim et al., 2012). Patients with elevated unbound iron in plasma are susceptible to mucormycosis. Mucoromycetes has the capacity to acquire iron from the host and interact and colonize the endothelial cells that line blood vessels (Ibrahim et al., 2012). Hemodialysis patients treated with the iron chelator deferoxamine are also susceptible to an invasive and deadly form of mucormycosis (Boelaert et al., 1991; Ibrahim et al., 2012). *Rhizopus* sp. secretes rhizoferrin, and this siderophore supplies iron to *Rhizopus* sp. through an energy-dependent process mediated by receptor. The iron plays a central role in mucormycosis infections, which causes extensive angioinvasion resulting in vessel thrombosis and subsequent tissue necrosis (Spellberg et al., 2005; Ibrahim et al., 2012). The route of invasion of mold infection is rhino-orbital-cerebral mucormycosis or pulmonary infection following hematogenous dissemination and CNS infection (McCarthy et al., 2014).

The dimorphic fungi: *Blastomyces dermatitidis*, *Coccidioides* spp., and *Histoplasma capsulatum*

Blastomyces spp. is a dimorphic fungal that presents the filamentous mold characteristics in the environment and present as a yeast in the human tissues. The conidia and fragments of the fungi can be inhaled, and inside of the lung, in the host the fungus convert fragments into pathogenic yeasts. *Blastomyces* sp. and other dimorphic fungi, including *H. capsulatum*, and *Coccidioides* spp. can survive inside the macrophages spreading the disease to the whole human body (McBride et al., 2017). Cerebral blastomycosis is a rare fungal disease triggered mainly by inhalation of conidia (Stavrakis et al., 2015). However, immunosuppressed patients are at risk for severe and disseminated blastomycosis disease (Ryan et al., 2019).

Coccidioidomycosis is a fungal infectious disease caused by the *Coccidioides* spp. The patients with T-helper2 lymphocytes dysfunction or immune deficiency have been found to be a risk factor of the disease. After inhalation and bloodstream dissemination, the spherules or endospores migrate to the meninges or into brain tissue triggering the CNS coccidioidomycosis. Histoplasmosis affects immunosuppressed patients, AIDS patients, transplant recipients, corticosteroid and tumor necrosis factor (TNF) antagonist therapies, and patients with ventriculoperitoneal shunts (Veeravagu et al., 2013; Góralaska et al., 2018). Histoplasmosis begins through spore inhalation, followed by a lung infection. In the sequence, the yeasts are phagocytized and spread inside of the immune cells in the host organism and into the CNS (Hariri et al., 2015).

The dematiaceous fungi: *Cladophialophora bantiana* and *Exophiala dermatitidis*

Dematiaceous fungi present a common route of transmission by inhalation or inoculation from surgery or trauma, with following hematogenous or contiguous spread into the CNS (Góralaska et al., 2018). The most important mechanism of pathogenicity of the phaeohyphomycosis is the presence of melanin in their cell walls that protect the fungi by the ROS and NS produced by the phagocytic cells (Gopalakrishnan et al., 2017). *Cladophialophora bantiana* is a melanized mycelial fungus mold that is a rare cause of human disease. The infection may start from the sinuses or via the bloodstream causing primary infection in the lung and disseminating to the CNS (Chakrabarti et al., 2016). *Cladophialophora* sp. presents a tropism to the CNS triggering phaeohyphomycosis in immunocompetent patients (Revankar et al., 2004). The neurotropic melanized *Exophiala dermatitidis* presents various properties. The fungus is extremophilic, oligotrophicity, assimilating volatile toluene and other aromatic or phenolic hydrocarbons as sole carbon sources. The CNS is a source of many monoaromatic catecholamine neurotransmitters, and it could be an explanation for the *Exophiala* sp. neurotropism (Lavrin et al., 2020). For more details, see Table 1.

Central nervous system immune response to fungal infection

The CNS is protected against toxins, drugs, and pathogens through the BBB and the intrinsic immune system of the brain (Koutsouras et al., 2017). Fungal infections in the CNS have become more common in the past two decades. Also, the fungal invasion in the CNS depends on the host's immune status, the ability of the fungi to avoid the immune system, and the virulence factors that facilitate the colonization and spread of the fungus. Fungi can cross the BBB through different mechanisms. The transcellular penetration involving either pinocytosis or receptor-mediated mechanisms to cross the endothelial cells; the *C. neoformans* and *C. albicans* use a transcellular mechanism to cross the BBB (Liu et al., 2011; Kronstad et al., 2011; Colombo and Rodrigues, 2015). Paracellularly, the pathogen crosses through intercellular junctions; for example, *C. neoformans*, *Aspergillus* sp., and *Fusarium* sp. In the Trojan-horse mechanism, the pathogen crosses the BBB internalized within an immune cell; for example, *C. neoformans* (Kronstad et al., 2011). For more details, see Fig. 1.

Glial cells, consisting of microglia, astrocytes, and oligodendrocytes, have several functions, including cerebral homeostasis, myelin production, BBB stability, and support and protection for neurons (Nimmerjahn et al., 2005). When the invading pathogen reaches the CNS, it provokes immediate and focal activation of CNS-resident cells. Microglia and astrocytes, together with

Immunocompetence	Meningitis, subpial ischemic lesions, brain abscess, epidural abscess, and mass lesions	Panackal and Williamson (2015), and McBride et al. (2019)
<i>Coccidioides immitis</i> 	<i>Coccidioides</i> spp. Phylum: Ascomycota	SOWgp, arginase I, coccidioidal urease, ammonia, and enzymatically active urease	Immunocompetence, T-helper 2 lymphocytes dysfunction, diabetes mellitus, and chronic steroid treatment	Meningoencephalitis, granulomatous meningitis, subpial ischemic lesions, and brain abscess	Panackal and Williamson (2015), Góralaska et al. (2018), and Hung et al. (2007)

Histoplasma capsulatum

Histoplasma capsulatum
Phylum:
Ascomycota

Capsule, CBP1, α -glucan, adhesins, CatA and CatB catalase protein, resistant to ROS and RNS, Eng1 and Exg8 β -Glucanases

Contamination by bird feces, immunocompetence, transplant recipients, corticosteroid and tumor necrosis factor antagonists, and patients with ventriculoperitoneal shunts

Meningitis, subpial ischemic lesions, and brain abscess

Veeravagu et al. (2013), Panackal and Williamson (2015), Hung et al. (2007), Edwards and Rappleye (2011), Mittal et al. (2019), Missall et al. (2004), and Garfoot et al. (2017)

Dematiaceous fungi
Cladophialophora bantiana

Cladophialophora sp.
Phylum:
Ascomycota

Melanin, extremophilic oligotrophicity, hydrolyzes peptides, urease, lipase, phospholipase, and DNase

Immunocompetence, transplant recipients, hematologic malignancy, tumors, and neutropenia

Brain abscess, granulomatous inflammation, meningitis, myelitis

Revankar et al. (2004) and Souza et al. (2008)

Exophiala dermatitidis

Exophiala sp.
Phylum:
Ascomycota

Melanin, extremophilic, oligotrophicity, hydrolyzes peptides, urease, lipase, phospholipase, and DNase

Immunocompetence, transplant recipients, hematologic malignancy, tumors, and neutropenia

Brain abscess, granulomatous inflammation, meningitis, myelitis, or encephalitis

Lavrin et al. (2020), Revankar et al. (2004), and Souza et al. (2008)

Abbreviations: BAD1, blastomyces adhesin-1; Cat, catalase gene; CDG, cysteine dioxygenase; DPPIVA, dipeptidyl-peptidase IVA; DRK1, dimorphism-regulating kinase; Eng1, endo-1,4-beta-glucanase; Exg8, *exo*- β 1,3-glucanase; GAG, galactosaminogalactan; GalXM, galactoxylomannan; GPx, glutathione peroxidase; GR, glutathione reductase; GXM, glucuronoxylomannan; NIC1, nickel transporter; PRA1, exogenous zinc uptake; RNS, reactive nitrogen species; ROS, reactive oxygen species; RYP1-4, required for yeast phase 1-4; Saps, secreted aspartic proteases; SOD, superoxide dismutase; SOWgp, spherule outer wall glycoprotein; SSU1, sulfite efflux pump; ZRT1, high-affinity zinc transporter; ZRT2, low-affinity zinc transporter.

Fig. 1 Types of mechanisms involved in the BBB fungal crossing. Pathogens can cross the blood-brain barrier transcellularly, paracellularly, or using the Trojan-horse strategy. In the transcellular mechanism, fungi cross the BBB between endothelial cells, such as *C. neoformans*, *C. albicans*, and *Trichosporon* sp. In the paracellular mechanisms, fungi, such as *Cryptococcus* sp., *Aspergillus* sp., *Fusarium* sp., and *Trichosporon* sp. they cross through intercellular junctions. The Trojan-horse mechanism fungi, such as *Cryptococcus* sp., reach the CNS and are transported in phagocytic cells.

peripheral immune cells, orchestrate the brain homeostasis and restoration (Dokalis and Prinz, 2019). Microglial cells recognize fungal compounds known as pathogen-associated molecular patterns (PAMPs). These PAMPs bind to pattern recognition receptors (PRRs) and non-PRRs, which are essential constituents of the immune system. The detection of PAMPs by immune receptors triggers a cascade of signaling pathways that activate various transcription factors and promote pro-inflammatory molecules production to eliminate invading fungi (Koutsouras et al., 2017).

Microglia, as a resident macrophage of the CNS, expresses Toll-like receptors (TLRs) 1 to 9 and C-type lectin receptors (CLRs), in which microglia is active after interaction with opsonized or non-opsonized fungal antigens. TLR-2 recognizes fungal β -glucans present in *Candida* spp., *C. neoformans*, *A. fumigatus*, and *H. capsulatum* (Camilli et al., 2018). The heterodimers TLR2/TLR1 and TLR2/TLR6 recognize GXM of the *C. neoformans*, and phospholipomannan (PLM) of the *C. albicans*. TLR4 recognizes O-linked mannans of *C. albicans*, GXM of *C. neoformans*, and *A. fumigatus* conidia (Koutsouras et al., 2017; Bourgeois and Kuchler, 2012). The endosomal TLR3, TLR7, and TLR9 recognize RNA or DNA of many fungi, including *C. albicans*, *C. neoformans*, and *A. fumigatus* (Bourgeois and Kuchler, 2012; Góralaska et al., 2018). The TLR1/TLR2, TLR6/TLR2, and TLR4 signal through the central pathway recruiting the myeloid differentiation factor (MyD)88-dependent adaptor protein that acts via nuclear factor- κ B (NF- κ B) to induce pro-inflammatory cytokines production (Broad et al., 2007). The cytokines production interferon (INF)- γ , TNF- α , interleukin (IL)-1 β , IL-6, and IL-12, and the chemokines play essential roles in preventing infection by inhibiting fungal growth and dissemination in the CNS (Broad et al., 2007; Góralaska et al., 2018). Microglia phagocytizes the *C. neoformans* and upregulates the expression of inducible nitric oxide synthase (iNOS) to eliminate the invasion pathogen (Drummond, 2017).

CLRs are an important class of receptors responsible to eliminate fungus infection. The most important CLRs are dectin-1, complement receptor 3 (CR3), mincle, and mannose receptor-1. Microglia expresses dectin-1, CR3, mincle, and mannose receptor-1 (McKimmie et al., 2006). Dectin-1 recognizes β -1,3-glucan of the *A. fumigatus*, *C. neoformans*, *H. capsulatum*, *Coccidioides* sp., *C. albicans*, *F. solani*, *E. rostratum*, *C. cladosporioides*, and *T. asahii* (Goyal et al., 2018). Dectin-1, together with TLRs, presents a synergism activating the NF- κ B to produces pro-inflammatory cytokines and exacerbating the ROS production to eliminate the invasion (Kasper et al., 1988; Goyal et al., 2018). CR3 on the surface of microglia recognizes mannose and β -glucans on the surface of *A. fumigatus* and *C. albicans* (Mogensen, 2009), increasing the phagocytosis and production of the ROS (Siew and Chern, 2018). Mincle recognizes *A. fumigatus*, and *C. albicans*, this receptor activates second messengers protein and the transcription factor NF- κ B to produces pro-inflammatory cytokines via the Syk/CARD9 pathway (Marakalala and Ndlovu, 2017; Richardson and Williams, 2014).

Brain infections, encephalitis, and meningitis: Fungus

Fungal infections of the CNS have a lower incidence when compared to viral infection or bacterial infection. However, fungal infections are severe and have a high mortality rate. The prevalence of the fungal neuro-infections disease is related to immunosuppressed and immunocompetent individuals, mainly hospitalized people and patients undergoing neurosurgery (Bongomin et al., 2017). In states where the patient has reduced immunity, BBB permeability increases, facilitating fungal penetration into the brain by paracellular, transcellular, and Trojan-horse mechanisms, Fig. 1. Fungi reach the brain parenchyma and proliferate, causing inflammation and cerebral infection. Since fungal pathogenic factors need to overcome the significant barriers surrounding the brain, invasions are mainly associated with the host's immunocompromised state (Sharma et al., 2012; Góralaska et al., 2018). The clinical syndromes of neuroinvasion caused by fungi are meningitis, meningoencephalitis, brain abscess, rhino-cerebral infection, and skull-base syndromes. Among the fungus that causes meningitis, we can list *Cryptococcus* sp., *Coccidioides* sp., *Exserohilum* sp., *Candida* sp., and *Histoplasma* sp. The incidence of meningoencephalitis is associated with *Cryptococcus* sp., *Coccidioides* sp., and *Candida* sp. In the brain, the abscess is listed *Aspergillus* sp., *Candida* sp., *Mucoromycetes* sp., *Blastomyces* sp., *Coccidioides* sp., and *Histoplasma* sp. The rhino-cerebral infection agents are *Mucor* sp., *Rhizopus* sp., *Absidia* sp., *Rhizomucor* sp., and *Syncephalastrum* sp. The skull-base syndromes are associated with *Aspergillus* sp. After a stroke or infarction, the main fungus systemically disseminated and

can reach the CNS are *Mucoromycetes* sp., *Aspergillus* sp., and disseminated mucoromycetes *Candida* sp., *Cryptococcus* sp., *Aspergillus* sp., *Coccidioides* sp., (Góralaska et al., 2018). For more details, see Table 1.

Conclusion

Fungal infections in the CNS remain a serious global health problem and pose a threat to the lives of patients. Besides, the clinical picture of manifestations of CNS infections caused by fungi are often unspecific and pose a challenge for diagnosis and treatment. In this article, we present the course and role of the immune response in cerebral fungal infection. A better understanding of the immunological pathways that are activated in an attempt to eliminate these pathogens, particularly in a cerebral context, is crucial and can provide insights for a faster diagnosis and, consequently, a better prognosis for patients affected by these severe infections. At the same time, it can assist the development of effective antifungal therapy to decrease mortality.

Introduction

Fungal meningitis is one of the possible clinical manifestations of invasive fungal diseases (IFDs) (Donnelly et al., 2020). Typically, IFDs are diagnosed in subjects with underlining medical conditions leading to alteration of the immune system caused by some diseases (i.e. human immunodeficiency virus (HIV)) or by the use of different medications leading to iatrogenic immune suppression (i.e. steroids, anti-rheumatic drugs, etc.) (Antinori and Giacomelli, 2020). Nevertheless, especially in recent years a rise in IFDs have been observed also in hosts without underling medical condition leading to immune system dysregulation (Vallabhaneni et al., 2016). Central nervous system involvement by fungi can manifest with focal intracerebral abscess(es), spinal cord lesions or more frequently with meningitis. Fungi can reach the central nervous system with different modalities: (1) hematogenous spread; (2) direct focal extension from anatomical regions such as paranasal sinuses, ear or orbits; (3) traumatic introduction. Fungal meningitis is a serious syndrome with an important burden of morbidity and mortality generally presenting as subacute or chronic meningitis (Table 1) (Pagliano et al., 2020). The incidence of fungal meningitis in England and Wales according to an 8-year observational study was 0.09/100,000 inhabitants (Okike et al., 2014). The authors reported only data regarding *Candida albicans* and non-*C. albicans* making impossible to infer regarding the incidence of other more frequent causes of fungal meningitis (i.e. *Cryptococcus* spp.). Moreover, it is likely that an underestimation of the real fungal meningitis burden occurred in this study (Antinori et al., 2014). In another study conducted in United States between 2000 and 2012 among fungal meningitis the most common causative organism was *Cryptococcus* spp. (70.1% of cases), followed by *Coccidioides* spp. (16.4%), *Histoplasma capsulatum* (6.0%) and *Candida* spp. (7.6%) (Charalambous et al., 2018). When considering the incidence estimates it should be considered that fungal meningitis is often underdiagnosed due to a low grade of suspect for fungal infection when meningitis is diagnosed outside selected populations (i.e. patients with underline immune system disorders) and standard cultures performed on cerebrospinal fluid (CSF) showed a low sensitivity for fungi (Barenfanger et al., 2004). Because infrequent, fungal meningitis requires a high suspicion index and an appropriate diagnostic workup to prompt diagnose and properly treat (Fig. 1). The epidemiology of the patient is important and an accurate anamnesis is fundamental to assess the potential exposure to contaminated environment, geographical areas with potential endemic fungi or to invasive procedures with the potential

Table 1 Fungal species responsible of meningitis.

Fungal species	Type of meningitis	Risk factors	Frequency
<i>Aspergillus</i> spp.	Acute meningitis	Neurosurgery, neutropenia	+
<i>Blastomyces dermatitidis</i>	Chronic meningitis	Travel/residence in endemic regions	-/+
<i>Candida</i> spp.	Subacute meningitis	Neurosurgery, premature newborn, CARD 9 deficiency	+
<i>Coccidioides immitis</i>	Subacute meningitis	Travel/residency in endemic regions, Hispanic, African and Asian background	+
<i>C. posadasii</i>	Chronic meningitis	Travel/residency in endemic regions, Hispanic, African and Asian background	+
<i>Cryptococcus neoformans</i>	Subacute meningitis	HIV infection	+++
	Chronic meningoencephalitis	Solid organ transplantation, immunosuppressive therapy	
<i>C. gattii</i>	Chronic meningoencephalitis	Travel/residency in endemic regions	++

inoculation of fungi in sterile sites. The implementation of additive laboratory tests other than cultures on CSF such as (1 → 3)-β-D-glucan, although non fungal specific, could increase the diagnostic accuracy (Davis et al., 2020).

In this narrative review we will focus on the most common causative agents of fungal meningitis starting from their epidemiology to pathogenesis, clinical manifestations, diagnosis and treatment.

Cryptococcosis

Microbiology and epidemiology

Cryptococcosis, first identified in 1894 by Otto Busse and Abraham Buschke, emerged as a major life-threatening meningoencephalitis with the onset of AIDS pandemic at the beginning of the 1980s (Williamson et al., 2017).

The initial attribution of a single fungal species named *Cryptococcus neoformans* has been challenged by phylogenetic and molecular studies that in 2002 led to classify *C. neoformans* var. *gattii* as a distinct species, *Cryptococcus gattii* (Kwon-Chung et al., 2002).

More recently, studies based on a multilocus sequence typing (MLST) and other molecular typing techniques showed a more complex taxonomic issue with the proposal of several separate species: *C. neoformans* (formerly *C. neoformans* var. *grubii*), *C. deneoformans* (formerly *C. neoformans* var. *neoformans*), *C. gattii* (VG1/AFLP4), *C. deuterogattii* (VGII/AFLP6), *C. bacillosporius* (VGIII/AFLP5), *C. tetragattii* (VGIV/AFLP7), *C. decagattii* (VGIV and VGIIIc/AFLP10) (Hagen et al., 2015, 2017; Kwon-Chung et al., 2017). To further complicate this taxonomic classification at least four diploid/aneuploidy hybrids have been recognized: AD (*C. neoformans* × *C. deneoformans*), DB (*C. deneoformans* × *C. gattii*), AB (*C. neoformans* × *C. gattii*) and AB (*C. neoformans* × *C. deuterogattii*) (Kwon-Chung et al., 2017).

Although cryptococcosis generally affects immunocompromised patients, with HIV/AIDS as the most common underlying condition, *C. gattii* is considered a true pathogen able to infect healthy immunocompetent individuals (Bielska and May, 2016; Franco-Paredes et al., 2015; Kronstad et al., 2011; Acheson et al., 2018).

It has been estimated that globally, cryptococcal meningitis was responsible for 15% of AIDS-related deaths and the most significant burden of the disease is in the Sub-Saharan Africa accounting for 73% of the estimated cryptococcal meningitis cases in 2014 (162,500 cases [95% CI 113,600–193,900]). Moreover, the annual global deaths from cryptococcal meningitis were estimated at 181,100 (95% CI 119,400–234,300), with 135,900 (75%; [95% CI 93,900–163,900]) deaths in sub-Saharan Africa (Rajasingham et al., 2017).

As far as *C. gattii*, this fungus has been considered to be endemic only in tropical and subtropical areas but, following the outbreak started in 1999 on Vancouver Island (British Columbia, Canada), it has been observed a more widespread geographic distribution including also temperate climate regions of Northern United States, Canada and Northern Europe (Herkert et al., 2017; MacDougall et al., 2007).

C. neoformans spores are particular abundant in bird's droppings as well in leaves and decaying woods whereas, *C. gattii* environmental niche is represented by different trees (especially Australian eucalyptus in tropical and subtropical regions and *Pseudotsuga menziesii* in temperate regions).

As previously mentioned HIV infection is the highest driven of cryptococcal meningitis but other risk factors (Table 2) such as solid organ transplantation (SOT) recipients and several heterogeneous HIV-negative/non-transplant (NHNT) conditions as well as some drug treatments have been identified to be as risk factors for cryptococcal meningitis (George et al., 2017; Marr et al., 2020; Bratton et al., 2012; Wald-dicker and Blodget, 2017; Singh et al., 2007; Brizendine et al., 2013; Williamson et al., 2017).

Two large retrospective studies conducted in the United States reported an overall incidence of cryptococcosis among SOT recipients of 0.2–0.37% (George et al., 2017; Pappas et al., 2010). In the setting of SOT, cryptococcosis is the third most common fungal infection, with a life time risk of 1–2%, presenting with meningitis in 44% to 60% of patients (George et al., 2017; Singh et al., 2007; Brizendine et al., 2013; Davis et al., 2009; Henao-Martínez and Beckham, 2015). Cryptococcosis is infrequent in the immediate post-transplant period being diagnosed after a median time from transplant of 20 to 26 months (Bratton et al., 2012; Pappas et al., 2010). An early onset of disease (occurring 30 days after transplantation) is observed in 10% of patients and it is sometime expression of donor-derived cryptococcal infection (George et al., 2017; Sun et al., 2010; Baddley et al., 2011, 2019). Lung transplantation recipients had the highest risk of cryptococcosis (Hazard ratio 2.1) compared with other organ transplant recipients (George et al., 2017). In NHNT cryptococcal meningitis is diagnosed in 34–43% of those with cryptococcal infection and for individuals taking immunosuppressive agents the median duration of drug exposure was 7 months (Bratton et al., 2012; George et al., 2018).

Pathogenesis

Cryptococcal infection occurs with the inhalation of both desiccated yeast cells (3 µm of size) and spores (1–2 µm of size) which are able to deposit deep in the alveoli of the lung (Kronstad et al., 2011). The next step following the pulmonary infection is the ability of *Cryptococcus* spp. to disseminate and cross the blood-brain barrier either by transcytosis and migration of phagocytic cells

Table 2 Predisposing conditions associated with non-HIV cryptococcal meningitis.

Predisposing conditions associated with non-HIV cryptococcal meningitis

- Solid organ transplant recipients
- Sarcoidosis
- Autoimmune diseases
- Chronic steroid treatment
- Idiopathic CD4+ lymphopenia
- Liver cirrhosis
- Autoantibodies to IFN-gamma
- Chronic granulomatous diseases
- Job syndrome (autosomal dominant hyper-IgE syndrome)
- Hyper IgM syndrome (X-linked CD40 L deficiency)
- Treatment with Bruton's tyrosine kinase inhibitors (ibrutinib)

containing the fungus thus causing a meningoencephalitis. The *Cryptococcus* spp. pathogenic mechanisms rely on the ability to replicate at 37 °C of temperature and on the ability to form an extracellular capsule. In particular, the polysaccharide capsule provides a physical barrier able to interfere with the macrophage phagocytosis and avoiding the clearance by the immune system (Bose et al., 2003). Moreover, phospholipase-B, laccases (LAC 1 and LAC 2) which catalyze melanin synthesis, and urease have been identified as potential additional virulence factors implicated in the dissemination of *Cryptococcus* spp. from the lung through the lymphatic system and blood to the central nervous system. In particular, both *C. neoformans* and *C. gattii* express phospholipase-B (Plb) enzyme B1 (PLB1) and the phosphatidylinositol (PI)-preferring phospholipase-C (Plc) which are involved in the fungal pathogenic mechanism (Djordjevic, 2010). Regarding the function of *Cryptococcus* spp. extracellular-bound urease (URE1), they show a role in the survival and multiplication of yeasts within the macrophages with potential implication in yeast crossing of epithelial and endothelial barriers (Feder et al., 2015). In addition, the emergence of an unusual lineage of *C. gattii* infecting otherwise healthy individuals first in Vancouver Island and then spread to the Canadian mainland and the Pacific Northwest shed new light on the evolution of pathogenic mechanisms. In this outbreak isolates comprise two distinct genotypes, one hypervirulent with an identical genotype that is unique to the Pacific Northwest and the other significantly less virulent and sharing an identical genotype of isolates from an Australian recombining population. These observations suggest that cryptic same-sex reproduction can enable expansion of a human pathogen to a new geographical niche and contribute to the ongoing production of infectious spores (Fraser et al., 2005). Another pathogenic factor related to hypervirulent strains (i.e. VGIIb clonal group) is the ability to proliferate within host macrophages where reactive oxygen species stimulate tubular mitochondrial morphology in a subset of cells, which appears to be a protective mechanism from autophagic degradation (Farrer et al., 2016). The genome plasticity of *Cryptococcus* spp. which relies in the modification of the number of chromosomes have been linked to virulence and the development of azole resistance (Farrer et al., 2013). The ability of the fungus to increase the number of azoles target (ERG11) or transporters (AFR1) lead to the development of azole-resistant strains (Kwon-Chung and Chang, 2012).

Clinical features

Cryptococcal meningitis presents usually with a subacute course over a period of days to weeks with a combination of several signs and symptoms including mild to moderate fever, headache, vomiting, cranial neuropathies, altered mentation, lethargy, memory loss, and signs of meningeal irritation (Table 3) (Maziarz and Perfect, 2016; Dromer et al., 2007; Hevey et al., 2019; Brizendine et al., 2013; George et al., 2018; Bratton et al., 2012; Antinori et al., 2001). However, the presentation is heterogeneous and in HIV infected subjects the onset could also be abrupt in the absence of signs of meningeal irritation but characterized by severe headache with high opening pressure at CSF examination (Fig. 2A–C). Due to the characteristics of the disseminated disease the patients with cryptococcal meningitis could present with a variable involvement of other sites such as lung, skin, eye, prostate, abdominal and bones (Antinori et al., 2020). The co-occurrence of meningeal involvement and focal cerebral lesions “criptococcoma” and/or obstructive hydrocephalus, frequently associated with *C. gattii* infection, suggest a poor prognosis and the patient could present with

Table 3 Clinical and mycological characteristics of cryptococcal meningitis in HIV positive patients, solid organ transplant recipients and HIV negative/non transplant.

Clinical and mycological parameters	HIV positive ^a %	SOT ^b %	NHNT ^c %
Meningitis or meningoencephalitis	69–88	42–60	34.4–50
Fever	44–70	40–49	28–49
Headache	57–73	43–50	40–44

Fig. 2 (A–C) Magnetic resonance findings in an AIDS presenter patient with disseminated cryptococcal disease with meningitis. The magnetic resonance imaging showed no meningeal contrast enhancement although the cerebrospinal fluid revealed a positive cryptococcal antigen, a positive India ink examination and the cerebrospinal culture turned positive. The cerebrospinal fluid examination revealed normal cell count and proteins level with only a reduced cerebrospinal on plasmatic glucose ratio.

signs of focal lesions (Fig. 3A–D) (Phillips et al., 2015). HIV negative patients present less frequently with meningitis and fever is observed in less than 50% of cases, a factor that can delay the diagnosis especially in SOT recipients with one quarter of patients diagnosed more than 1 month after symptoms onset (Marr et al., 2020). A delayed diagnosis of cryptococcal meningitis has been associated with long-term neurological deficits (i.e. hearing and visual loss, ataxia, seizures) (Aye et al., 2016). CSF examination in cryptococcal meningitis include a raised opening pressure (more frequently in HIV-positive patients), a mild elevated white cell count with lymphocyte predominance, low CSF glucose and elevated CSF protein (Kashef Hamadani et al., 2018; Dromer et al., 2007; Antinori et al., 2001; Tseng et al., 2013). However, in HIV-associated cryptococcal meningitis the CSF white cell count is generally lower and can be normal in comparison with HIV negative individuals (Jarvis et al., 2014; Antinori et al., 2001; Dromer et al., 2007). Moreover, the rate of positive CSF cultures, positive CSF cryptococcal antigen (CrAg) and positive India ink are higher among HIV positive patients. Significantly higher CrAg titer either in serum and CSF are observed in HIV infected subjects than NHNT subjects and transplant recipients probably as expression of more severe immunodeficiency and fungal burden (Hevey et al., 2019; Dromer et al., 2007; Tseng et al., 2013). An important complication of cryptococcal meningitis identified both in HIV positive patients and SOT recipients is the immune restoration inflammatory syndrome (IRIS), the presentation of which mimics worsening or relapsing cryptococcal diseases (paradoxical IRIS) or the “de novo” diagnosis of cryptococcal meningitis in HIV-positive subjects with subclinical cryptococcal disease once the antiretroviral therapy is started (unmasking IRIS) (Lortholary et al., 2005; Bicanic et al., 2009; Antinori et al., 2009; Singh, 2012; Haddow et al., 2010). In a study conducted in United States which included the three groups of patients with cryptococcosis, the prevalence of IRIS was 3% although higher prevalence has been reported either in AIDS patients (8–19%) and SOT recipients (5–11%) (Bratton et al., 2012; Lortholary et al., 2005; Bicanic et al., 2009; Antinori et al., 2009; Singh, 2012).

Diagnosis

The initial diagnostic workup relies on a high index of clinical suspicion derived from an appropriate medical history. The gold standard is the isolation of *Cryptococcus* spp. from a sterile site (i.e. CSF, blood). In HIV positive patients with cryptococcal meningitis CSF and blood cultures are positive in up to 90% and 70% of patients, respectively (Antinori, 2013). Moreover, the CSF negativity on antifungal treatment has prognostic implication and the quantitative culture on CSF correlate with survival (Bicanic et al., 2007). The diagnosis could be reached also with antigenic assays on cerebrospinal fluid and blood combined with the direct examination of the CSF by India ink stain. The sensitivity reported for India ink depends mainly on the fungal burden and consequently is higher, up to 80%, in people living with HIV who developed AIDS when compared to non-AIDS patients (below 60%) (Antinori, 2013). The diagnostic capacity significantly improved with the introduction of methods who searched for the cryptococcal polysaccharide capsular antigen (CrAg), which is shed during infection. Latex agglutination and enzyme immunoassay performed on serum and CSF samples showed an overall sensitivities and specificities of 93% to 100% and 93% to 98%, respectively (Wu and Koo, 1983; Tanner et al., 1994). More recently, a lateral flow assay was approved for use in serum and CSF, with sensitivity and specificity of greater than 98% in both specimen types (including whole blood from finger stick samples) and sensitivity of 85% in urine (Jarvis et al., 2011; Huang et al., 2015). The histopathology could be helpful in selected cases (i.e. bone or soft tissue involvement) or when an initial diagnosis due to poor suspicion index is not reached. In the end molecular methods are mainly used for research purposes and are to date not yet implemented in clinical practice.

Treatment

The therapeutic strategy for cryptococcal meningitis relies on appropriate antifungal treatment and in patients with AIDS with the choice of an appropriate timing of antiretroviral start to minimize the risk of IRIS (van der Horst et al., 1997). The treatment of

Fig. 3 (A–D) Magnetic resonance findings in an AIDS presenter patients presenting with worsening headache, multiple cutaneous lesion and pneumonia. The MR showed multiple contrast enhanced lesions compatible with opportunistic infection of the brain parenchyma. Blood cultures turned positive for *Cryptococcus neoformans* var. *neoformans*.

Table 4 Treatment option for cryptococcal meningitis.

Phase	First drug options	Alternative options	Administration route	Duration
Induction	Liposomal amphotericin B 3–4 mg/kg or amphotericin B deoxycholate 0.7–1 mg/kg/day and 5-flucytosine 100 mg/kg/day	Liposomal amphotericin B 3–4 mg/kg or amphotericin B deoxycholate 0.7–1 mg/kg/daily and fluconazole 800–1200 mg/daily	Iv + Os	HIV +: 2 weeks SOT: ≥2 weeks All other patients ^a : 4–6 weeks
Consolidation	Fluconazole 400 mg/daily	Itraconazole 400 mg/daily	Os	At least 8 weeks
Maintenance	Fluconazole 200 mg/daily		Os	At least 12 months ^b

Iv, intravenous; Os, oral subadministration; HIV, human immunodeficiency virus; SOT, solid organ transplantation.

^aIncluding patients with *Cryptococcus gattii* infection.

^bIn HIV-positive patients consider discontinuation of maintenance if CD4 cells count is >100 cell/μL and HIV-RNA is suppressed for more than 3–6 months.

cryptococcal meningitis consists on three phases: induction, consolidation, and maintenance therapy (Table 4). The induction phase aims to achieve rapid fungicidal activity to obtain CSF sterility using the combination of amphotericin B deoxycholate (amB) (0.7 mg/kg/day) and 5-flucytosine (5-FC) (100 mg/kg/day) for 2 weeks. The combination of amB and 5-FC is more rapidly fungicidal than amB alone and is associated with a trend toward a higher proportion of patients achieving a sterile CSF at 2 weeks and a reduced relapse rate (van der Horst et al., 1997; Perfect et al., 2010). The consolidation phase is the subsequent 8-week treatment period with either fluconazole (400 mg/day) or itraconazole (400 mg/day) as an alternative for patients with fluconazole intolerance. The maintenance phase is crucial in people living with HIV to avoid relapses. Oral fluconazole at a dosage of 200 mg/day has been shown to be superior to placebo (Bozzette et al., 1991) and both weekly intravenous amB (Powderly et al., 1992) and oral itraconazole (Saag et al., 1999) and should be continued for at least 1 year. After that the discontinuation of maintenance therapy could be considered in those with an HIV-RNA below 50 cp/mL for at least 3 months and a CD4 cell count above 100 cell/μL. It has been demonstrated that the substitution of amB deoxycholate with liposomal amB does not reduce the

probability of therapeutic success and is associated with better tolerability in particular by reducing the probability of kidney toxicity. Consequently, where available, the liposomal formulations of amB are now the preferred first line options (Hamill et al., 2010; Migone et al., 2018).

Regarding the correct choice of antiretroviral start in people living with HIV with cryptococcal meningitis international guidelines (Panel on Guidelines for the Prevention and Treatment of Opportunistic Infections in Adults and Adolescents with HIV (2020)) suggest an optimal administration time between 2 and 10 weeks after the start of antifungal therapy with the precise starting dates based on individual conditions and local experience and preferably after 5 weeks. The latter recommendation is based on a randomized clinical trial showing an increased probability of survival in those delaying the antiretroviral initiation after 5 weeks (Boulware et al., 2014).

The treatment in patients with SOT and receiving immunosuppressant treatment follow the same scheme of that of people living with HIV. The management of the immunosuppressant should take into account the risk of IRIS also in these patients (Singh et al., 2005). The treatment of non-HIV and without underline classical risk factors is complicated by the usual late presentation of these patients.

The management of intracranial pressure in patients with cryptococcal meningitis is crucial because a CSF opening pressure of more than 250 mmH₂O is associated with an increased mortality and over a quarter of HIV positive patients presents with a very high intracranial pressure (Rolfes et al., 2014; Jarvis et al., 2014; Graybill et al., 2000). Therefore, when raised intracranial pressure is observed several international treatment guidelines recommended to perform repeated therapeutic lumbar punctures ad adjunctive management (Chang and Perfect, 2016). Surgical management of intracranial pressure with either external lumbar drainage or ventriculoperitoneal shunting has been reported in case series but specific rules for their use are still lacking (Woodworth et al., 2005; Bach et al., 1997; Park et al., 1999; Cherian et al., 2016; Manosuthi et al., 2008).

Outcomes

Despite aggressive treatment a significant proportion of patients with cryptococcal meningitis persists with poor outcomes and neurological disabilities. In a study from United States, the overall mortality rate was 28.8% with a 90-day mortality rate higher for NHNT subjects (20.7%) in comparison with HIV infected (14.6%) and SOT recipients (13.7%) ($P < .001$) (George et al., 2018). Moreover, the overall mortality was also higher among NHNT subjects (33.2%) and SOT recipients (37.2%) than in HIV positive patients (25%). Possible explanation for the worst outcome among HIV negative included advanced age, underlying comorbid disease and delayed diagnosis (George et al., 2018; Brizendine et al., 2013). In a retrospective cohort study, patients with end-stage liver disease had a significantly higher mortality than HIV positive and HIV negative patients (80% vs 13.6% vs 22.7%, respectively; $P < .001$) (Spec et al., 2015). A systematic literature review showed that in HIV associated cryptococcal meningitis the main independent risk factor for long term mortality were an abnormal neurological status, high CSF fungal burden, low CD4+ cell count and older age at diagnosis (Pasquier et al., 2018). Among HIV-negative patients with cryptococcal meningitis, the main independent risk factors for 1-year mortality were delayed diagnosis, altered neurological status, high CSF CrAg and non-amB based induction therapy (Pasquier et al., 2018).

Candidiasis

Epidemiology and clinical manifestations

Meningitis caused by *Candida* spp. is an uncommon clinical entity usually related to the presence of an iatrogenic predisposing condition such as a neurosurgical procedure with the placement of a shunt or an intracranial device (Nguyen and Yu, 1995). In a 12-year study from Brazil, *Candida* spp. meningitis represented only 1.1% of death attributed to fungal meningitis and 0.05% of all deaths due to meningitis (Alves Soares et al., 2019). Moreover, in this setting the previous exposure to broad spectrum antibiotics is a quite common event (Nguyen and Yu, 1995). Among the infections of shunts and intracranial devices *Candida* spp. infections represent only a minority with a so far higher prevalence of bacterial infections. In a recent case series of 24 patients with *Candida* spp. involving the central nervous system the attributed overall mortality was 42%: 53% in case of disseminated infection and 14% in case of localized infection. In the same series the most frequent causative agent was *C. albicans* (70%) followed by *C. tropicalis* and *C. parapsilosis* (Chaussade et al., 2020). CSF analysis in case of *Candida* spp. meningitis shows high cellularity with either neutrophil or lymphocyte predominance (Casado et al., 1997; Sánchez-Portocarrero et al., 1994; Goldani and Santos, 2010); hypoglycorrhachia is observed in 50% of cases and CSF culture is also positive in half of patients (Chaussade et al., 2020). Fever and intracranial hypertension are observed in 86% of patients. In another case series of 11 central nervous system candidiasis following neurosurgery *C. albicans* accounted for 73% of episodes. All the infections were associated with foreign intracranial material (external ventricular drains in 82%). In the same study a mortality up to 30% was reported (O'Brien et al., 2011).

Candidiasis of the central nervous system is a rare clinical entity which can be observed also in neonate and premature infants with predisposing conditions (shunt/intracranial devices/broad spectrum antibiotics) and children affected by hematologic malignancy and primary immune deficiencies following haematogenous spread with a consequent central nervous system seeding (Walsh et al., 2019). Haematogenous disseminated *Candida* meningoencephalitis is a life-threatening infection with the potential of serious neurologic morbidity if not recognized and treated early. In a case series of 12 children with cancer *C. tropicalis* accounted for 11 out of 12 central nervous system infections (McCullers et al., 2000).

Pathogenesis

The pathogenic mechanism underlying the *Candida* spp. penetration into the subarachnoid space is the direct inoculation of the fungus through contaminated instruments or the disruption of the natural blood-brain-barriers combined with the presence of device which creates a milieu for yeast attachment and proliferation. Haematogenous seeding is another important mechanism through which the yeast disseminates in central nervous system. Moreover, *Candida* spp. are able to produce a biofilm which protect the fungus from the immune-system protective mechanism such as phagocytosis and oxidative stress (Cavalheiro and Teixeira, 2018).

Diagnosis

The detection of $(1 \rightarrow 3)$ - β -D-glucan on CSF in *Candida* spp. meningitis is an early diagnostic indicator which could also be helpful for the subsequent therapeutic management (Salvatore et al., 2016; Lyons et al., 2015). The definite diagnosis is reached when *Candida* spp. is isolated from a sterile site such as blood and CSF but CSF culture is relative insensitive. The resistance pattern of the fungus is crucial to guide the treatment. The diagnostic workup of candidiasis of the central nervous system requires the inclusion of diagnostic procedures to exclude the presence of other septic sites (i.e. endocarditis) or localized region (i.e. brain abscess, eye and abdominal localization).

Treatment

The treatment of central nervous system is based on liposomal amB, 5 mg/kg daily, with or without oral 5-FC, 25 mg/kg four times daily. Fluconazole 400–800 mg (6–12 mg/kg) daily is recommended after response to the initial treatment as step-down therapy after the patient has responded to initial treatment and should be continued until symptoms have been resolved such as the radiological abnormalities. A prompt evaluation of the infected central nervous system devices should be performed with the aim to remove the infected focus. If not possible, amB deoxycholate could be administered through the device into the ventricle at a dosage ranging from 0.01 to 0.5 mg in 2 mL 5% dextrose in water (Pappas et al., 2016). The preferred regimen for neonates is amB deoxycholate, 1 mg/kg intravenous daily with liposomal amB, 5 mg/kg daily, as an alternative. The step-down treatment is recommended with fluconazole, 12 mg/kg daily, if the clinical isolate is susceptible (Pappas et al., 2016).

Aspergillosis

Epidemiology and clinical presentation

Aspergillus spp. meningitis is an extremely rare clinical entity which can occur both in immunocompetent and immunocompromised hosts with a case fatality rate up to 72% (Antinori et al., 2013). The most frequent causative agent is *A. fumigatus* followed by *A. flavus* and *A. terreus*. The most common clinical presentation is acute meningitis, followed by meningoencephalitis. Meningeal signs are uncommon and when present are indicative of subarachnoid hemorrhage (McCarthy et al., 2014; Ma et al., 2020). Headache is frequent in 56.5% of patients with *Aspergillus* spp. meningitis associated with visual loss (39.1%), diplopia (35.8%) and hemiplegia (13%) (Ma et al., 2020). Chronic meningitis could also be observed especially in immunocompetent hosts with a subacute onset with mild symptoms. The evolution of *Aspergillus* spp. meningitis could include spinal arachnoiditis, ventriculitis and the formation of a granuloma or an abscess (McCarthy et al., 2014).

Pathogenesis

Central nervous system aspergillosis is usually associated with classical risk factors such as neutropenia and high dose steroids. Nevertheless, in the cases observed in immunocompetent hosts a direct route through the subarachnoid space was usually found (i.e. direct seeding from contiguous sites such as orbital or sinus tract infection, neurosurgical procedures, spinal anesthesia) (Antinori et al., 2013). Moreover, also the haematogenous dissemination is possible in intravenous drug users or in those with infective endocarditis (Antinori et al., 2013).

Diagnosis

The culture performed on CSF shows low sensitivity and often requires multiple attempts to turn positive. The diagnosis is quite often reached after autopsy in misdiagnosed cases. The probability of a positive culture is higher in immunocompetent hosts (36.9%) when compared to those with immune system impairment (18.2%) (Antinori et al., 2013). The CSF examination usually reveals pleocytosis with a predominance of granulocytes and hypoglycorrhachia. The galactomannan antigen could be helpful during the diagnostic workup if turned positive on serum whereas, due to the absence of standardized cut-off, the results on CSF are difficult to be interpreted (Verweij et al., 1999; Viscoli et al., 2002). Moreover, the diagnostic accuracy of $(1 \rightarrow 3)$ - β -D-glucan on cerebrospinal fluid is still unclear with only anecdotal reports (Davis et al., 2020). The PCR performed on CSF in subject with hematologic disorders showed a good sensitivity (100%) and specificity (93%) but it is not widely implemented (Hummel et al., 2006; Reinwald et al., 2013).

Treatment

The first line regimen is based on voriconazole starting with 6 mg/kg iv every 12 h the first day followed by 4 mg/kg iv every 12 h (Schwartz et al., 2005) with a recommended therapeutic trough concentration between 2 and 5.5 mg/L. Liposomal amB at the dosage of 3–5 mg/kg daily should be considered as an alternative option (Ullmann et al., 2018). The treatment duration should be tailored according to treatment response and clinical improvement. In case of focal lesions or signs of intracranial hypertension a neurosurgical evaluation is warranted.

Endemic mycoses

Certain fungi which are endemic in some areas because of high concentration in the environment are able to cause IFDs with meningitis (Kauffman, 2019; Ashraf et al., 2020). Among these, *Coccidioides* spp., *Paracoccidioides* spp., *Histoplasma* spp., *Talaromyces* spp., *Sporothrix* spp. and *Blastomyces* spp. are able to cause IFDs both in immunocompetent and in immunocompromised hosts (Challa, 2020). A schematic representation of the recommended antifungal treatment for meningitis caused by endemic mycoses is reported in Table 5.

Talaromycosis

Talaromycosis is caused by the dimorphic fungus *Talaromyces* (previously *Penicillium*) *marneffe* which is endemic in China and South East Asia. The fungus is widely distributed in soil and it could be found in several species of bamboo rats (Nelson et al., 2011). The burden of *T. marneffe* infections significantly increased with the HIV epidemic (Duong, 1996). Nevertheless, the risk is also increased in those receiving immunosuppressive agents in particular TNF- α inhibitors (Chan et al., 2015; Antinori et al., 2020). Talaromycosis could seldom be observed also in immunocompetent hosts.

The fungus is acquired through inhalation and after the entrance in the lung it is disseminated by the reticuloendothelial system. The vast majority of infections run asymptomatic in those with an intact T cellular immunity. The occurrence of meningitis in subjects with disseminated *T. marneffe* infection is a very uncommon event (Le et al., 2010). The diagnosis is made by the isolation of the pathogen from sterile sites (blood and CSF) or by the culture or histopathologic examination of skin samples. The usual CSF findings are mild cellularity, slight protein increase and a normal or reduced glucose level. The treatment of talaromycosis is based on liposomal amB 5 mg/kg daily for 4–6 weeks followed by a step-down therapy with oral itraconazole 200 mg twice daily or higher to achieve trough serum concentrations above 2 μ g/mL.

Table 5 Treatment regimens for meningitis caused by endemic mycoses.

Meningitis caused by endemic mycoses	Treatment induction	Step-down	Notes
Talaromycosis	Liposomal amphotericin B 5 mg/kg daily for 4–6 weeks	Itraconazole 200 mg per os every 12 h until CD > 100 cell/ μ L for at least 6 months	– Trough concentration of itraconazole >2 μ g/mL
Blastomycosis	Liposomal amphotericin B 5 mg/kg daily for 4–6 weeks	Itraconazole 200 mg per os every 12 h for 12 months or voriconazole 200–400 mg every 12 h	– Alternative regimen for induction voriconazole – Lifelong treatment in immunosuppressed patients should be considered
Paracoccidioidomycosis	Liposomal amphotericin B 5 mg/kg daily for 4–6 weeks	Itraconazole 200 mg per os every 12 h for 12 months	– Monitor trough concentration of azoles during step-down treatment – Alternative step-down therapy with voriconazole or trimethoprim/sulfamethoxazole
Coccidioidomycosis	Fluconazole 400–1200 mg per os daily	Chronic azole treatment	– Life long suppressive treatment with trimethoprim/sulfamethoxazole should be considered – Alternative regimens based on itraconazole, voriconazole, isavuconazole and liposomal amphotericin B – Refractory cases could be treated with intrathecal amphotericin B
Sporotrichosis	Liposomal amphotericin B 5 mg/kg daily for 4–6 weeks	Itraconazole 200 mg per os every 12 h for 12 months	– Lifelong suppressive therapy is recommended – Lifelong treatment in immunosuppressed patients should be considered
Histoplasmosis	Liposomal amphotericin B 5 mg/kg daily for 4–6 weeks	Itraconazole 200 mg per os every 12 h for 12 months	– Lifelong treatment in immunosuppressed patients should be considered

Coccidioidomycosis

Coccidioidomycosis is an endemic mycosis caused by the soil-dwelling fungi *Coccidioides immitis* and *C. posadasii* which are only present in the western hemisphere (Johnson and Einstein, 2006). Although the clinical presentation of the disease is the same between the two species, *C. immitis* is more common in California, and *C. posadasii* is more common in Texas, Central and Latin America (McCotter et al., 2019). The number of reported coccidioidomycosis cases has increased in recent years probably due to environmental changes in endemic area combined with an increasing number of immunocompromised hosts (Brown et al., 2013).

The vast majority of *Coccidioides* spp. infections run asymptomatic. Nevertheless, influenza like illness is common such as symptoms deriving from a mild primary lung involvement. A small percentage of subjects develop the disseminate form of the disease. Lymphohematogenous spread to the leptomeninges almost always occurs within weeks to months following the initial untreated lower respiratory infection and frequently involves areas of the basilar, sylvian, and interhemispheric cisterns (Wrobel et al., 1992). The clinical presentation is usually subacute or chronic. *Coccidioides* spp. and the course of the disease is usually insidious because headache may not be severe, the main hallmark being its persistence over weeks or months. In a case series of 71 patients from a referral center from Arizona headache was present in 77% of cases whereas neck rigidity was found in only 23% (Drake and Adam, 2009). As the disease progress undiagnosed, the patients develop confusion, emotional lability, disorientation, diplopia and grit disturbances. At physical examination nuchal rigidity is uncommonly observed but subjects show slowed speech and cognitive disturbances (Bouza et al., 1981; Drake and Adam, 2009; Kelly, 1980). Nearly 40% of patients with coccidioid meningitis will present or develop hydrocephalus which is the most common complication of this meningitis and a major contributor of mortality (Blair, 2009; Galgiani et al., 2016). Vasculitic infarction are observed in 10% of patients with stroke (aphasia, hemianopsia, hemiparesis) as clinical picture of presentation (Williams et al., 1992). Lumbar pain, neurological bladder, paraplegia and quadriplegia are the expression of arachnoiditis (Mathisen et al., 2010).

Neuroimaging studies (preferably gadolinium enhanced magnetic resonance scan) are an essential part of the work-up of suspected coccidioid meningitis (Wrobel et al., 1992; Arsura et al., 2005). Leptomeningeal enhancement of the basilar cistern is observed in 91% of cases and hydrocephalus in 78% (Lammering et al., 2013). The high frequency of spinal involvement (37% nerve root clumping, 16% intramedullary and spinal cord hyperintensity on T2 signal, 16% with intradural masses) suggests the need to make both intracranial and spinal imaging for patients with coccidioid meningitis (Crete et al., 2018).

Because untreated meningitis is nearly always fatal, early diagnosis and initiation of therapy is important to prevent death and many of the complications that ongoing meningeal inflammation produces (Vincent et al., 1993).

Coccidioid meningitis diagnosis requires laboratory analysis of the CSF, a must in patients with a diagnosis of coccidioidomycosis with persistent headache. The CSF findings of coccidioid meningitis include cellular pleocytosis (between 20 and 200 cell/ μ L). CSF examination usually shows a lymphocytic predominance but CSF eosinophilia is considered suggestive (Jackson et al., 2019; Ragland et al., 1993) and hypoglycorrhachia is frequent and severe (Drake and Adam, 2009). The definite diagnosis could be reached by the culture and isolation of *Coccidioides* spp. from CSF but it is positive in less than one third of cases. Several non-culture techniques can be employed to diagnose coccidioid meningitis (Binnicker et al., 2011). A classical assay is the complement fixation (CF) coccidioid antibody test based on a complement-fixing methods or immunodiffusion (ID). This test detects IgG antibody and is positive in over 95% of patients with coccidioid meningitis (Pappagianis and Zimmer, 1990; Pappagianis, 2001). In the largest study so far conducted, the CF with ID had a sensitivity of 78%, 100% specificity and positive predictive value and 74% negative predictive value (Stevens et al., 2020). Interestingly, a lateral flow assay (one strip and two strip) showed the highest sensitivity (92–95%) and specificity (100%) with a negative predictive value of 86–91%. Beta-D-glucan (with a cut of 31 pg/mL) had a good sensitivity (96%) but a lower specificity (82%) and a negative predictive value (90%) (Stevens et al., 2020).

The best available treatment for coccidioid meningitis is fluconazole at the recommended dose of 400 mg daily although some experts would prefer an initial dose of 800 mg daily (Tucker et al., 1990; Jackson et al., 2019). A maintenance therapy (fluconazole 400 mg) should be continued life-long to avoid the high rate of relapse (80%) observed in patients discontinuing it (Dewsnup et al., 1996). All the other azole (itraconazole 400–800 mg daily, voriconazole 4 mg/kg every 12 h, posaconazole oral suspension 400 mg every 12 h, isavuconazole) can be used as an alternative therapy for coccidioid meningitis (Johnson et al., 2018).

Paracoccidioides

Paracoccidioidomycosis is caused by two species *Paracoccidioides brasiliensis* and *P. lutzii* (Hahn et al., 2019). The epidemiology of paracoccidioidomycosis is restricted to Latin America with most of cases reported in Brazil (*P. lutzii* near the Mato Grosso region), Argentina, Venezuela, Ecuador, and Colombia (Martinez, 2017). Such as for other endemic mycoses with a direct relation to soil exposure the disease is more often reported in men without apparent underlying medical conditions. Nevertheless, in recent years the disease is increasingly observed in people living with HIV (Morejón et al., 2009) such as in SOT (de Almeida Jr et al., 2018). Due to the latency of the fungus, the infection could be acquired during the childhood and then reactivate in case of immune suppression. The central nervous system involvement is uncommon in paracoccidioidomycosis (<15% of patients) and more often observed in the chronic form of the disease with space-occupying lesions. Meningitis is a very infrequent manifestation of this endemic mycosis and is a consequence of a disseminated form of the disease both in acute or chronic cases (Elias Jr et al., 2005).

The diagnosis could be reached by the isolation of the fungus from CSF or by a positive culture or histopathology on tissue obtained by a brain biopsy (Elias Jr et al., 2005). The detection of a circulating antigens (gp43 and gp70) of *P. brasiliensis* in serum and CSF has been suggested as a diagnostic method (da Silva et al., 2005). Nevertheless, the diagnosis is often presumptive when *Paracoccidioides* spp. is isolated from other sites and symptoms of central nervous system involvement are present.

The treatment is based on liposomal amB (5 mg/kg daily for 4–6 weeks) followed by itraconazole for at least 12 months. In some circumstances, i.e. immunosuppressed patients, a suppressive lifelong treatment with trimethoprim/sulfamethoxazole should be considered (Shikanai-Yasuda et al., 2017).

Histoplasmosis

Histoplasmosis is a disease caused by the fungus *Histoplasma capsulatum*. *H. capsulatum* var. *capsulatum* is widely distributed whereas *H. capsulatum* var. *duboisii* is limited to sub-Saharan Africa. The disease is highly endemic in some regions of North America, Central America, and South America but it is also reported in certain countries of Asia such as China, India and Thailand (Antinori, 2014; Bahr et al., 2015). Histoplasmosis more often involves subjects with underlying medical conditions and in particular people living with HIV causing approximately 10–15% of AIDS related deaths in the Americas (Pan American Health Organization and World Health Organization, 2020). In particular, in such patients the clinical characteristic of disseminated histoplasmosis makes the differential diagnosis with tuberculosis extremely difficult.

Central nervous system involvement occurs in 5–10% of disseminated histoplasmosis cases (Wheat et al., 2018) and the most frequent clinical feature is represented by chronic meningitis with or without focal brain, or spinal cord lesions, stroke syndromes, encephalitis, and hydrocephalus (Wheat et al., 2007). It is worth mentioning that approximately one third of subjects affected by central nervous system histoplasmosis have no underlying medical conditions leading to immunosuppression (Wheat et al., 2018). Although histoplasmosis involving the central nervous system was first described in 1934, it was not until 1990 that a clinical series reported the clinical course of patients with central nervous system histoplasmosis (Wheat et al., 1990). In this case series meningismus was described in only 8% of patients whereas in a more recent study by Wheat et al. neck rigidity was observed in 13% of patients (Wheat et al., 1990, 2018).

The diagnosis of *Histoplasma* spp. meningitis is delayed as observed in case of chronic meningitis with only 26% of patients presenting with symptoms for 2 weeks or less (Wheat et al., 1990, 2018). CSF findings show a lymphocytic pleocytosis in 50% of cases but a predominance of neutrophils occurs in 11% of cases; low glucose level (<40 mg/dL) are reported in 53% of patients.

Histoplasma spp. can be isolated from fungal culture of CSF in approximately 25% of cases. Moreover, the slow growing nature of this fungus often causes a treatment delay (Wheat et al., 2018). The most sensitive method for diagnosis of central nervous system histoplasmosis is based on the detection of antibody and antigen in the CSF. The combination of both the assays lead to an accuracy of 98% in detecting central nervous system histoplasmosis cases (Bloch et al., 2018). As expected, the sensitivity of antigen detection in central nervous system histoplasmosis was better among immunocompromised patients (81%) in comparison with those not immunocompromised (31%) and in patients with more severe disease (93% vs 55%) (Wheat et al., 2018). According to a recent study the sensitivity of *Histoplasma* antigen detection in CSF was 78% with a specificity of 93% (Bloch et al., 2018).

The treatment of *H. capsulatum* meningitis requires a prompt antifungal treatment with liposomal amB followed by itraconazole for at least 12 months. As for other endemic mycoses a suppressive lifelong treatment with azoles should be considered (Wheat et al., 2007).

Blastomycosis

Blastomycosis is an infection caused by several species of a dimorphic fungus named *Blastomyces*. The fungus able to cause human diseases are *B. dermatitidis*, *B. gilchristii* and *B. helicus* (Schwartz et al., 2019). The fungus lives in the environment, particularly in moist soil and in decomposing matter in the United States and Canada, in particular around the Ohio and Mississippi River valleys and the Great Lakes. The cases are more often sporadic and it could be possible to observe outbreaks when an epidemiological link between subjects is present, i.e. work activities involving soil disruption in endemic area. Probably due to working exposure to contaminated environment blastomycosis is more often observed in men.

Blastomyces spp. disseminate through the lung and the central nervous system involvement is less common when compared to other endemic mycoses. The clinical manifestation of central nervous system involvement comprehends both space occupying-lesions and/or meningitis, meningoencephalitis (Gonyea, 1978; Bariola et al., 2011; Bush et al., 2013). The central nervous system involvement is more frequent in immunocompromised patients and it is estimated that occur in 1–10% of patients with blastomycosis (Pappas et al., 1992; Chapman, 2005) but it could seldom be observed in hosts without underlying medical conditions (Bush et al., 2013). The clinical manifestations of meningitis caused by *Blastomyces* spp. range from a chronic syndrome with headache, mental status alteration and signs of raised intracranial pressure to a disseminated disease characterized by multiple organ involvement more often observed in immunocompromised individuals (Kauffman, 2019).

The definite diagnosis is obtained by the isolation of the fungus from a sterile site such as blood or CSF. Due to the slow growing nature of *Blastomyces* spp. the diagnosis is often reached by the histological examination of tissues in disseminated diseases with the help of silver or periodic acid Schiff (PAS) colorations. Moreover, a presumptive diagnosis could be inferred by the positivity of *B. dermatitidis* antigen on serum or urine (Bariola et al., 2011). The specific antigen could also be searched in the cerebrospinal fluid (Bariola et al., 2010). The galactomannan antigen could be helpful but it is worth mentioning the cross-reactivity with another endemic fungus, *H. capsulatum*. Liposomal amB is the drug of choice for the initial phase of treatment followed by a prolonged treatment with azoles for at least 12 months. In those subjects with underlying immune systems disorders a life-long antifungal treatment should be considered (Chapman et al., 2008).

Sporotrichosis

Sporotrichosis is a ubiquitous mycosis caused by a complex of six phylogenetically different dimorphic fungi, including *Sporothrix schenckii* sensu stricto, *S. albicans*, *S. brasiliensis* (in Brazil), *S. mexicana* (in Mexico), *S. globosa* (in United Kingdom, Spain, Italy, China, Japan, United States, and India) (Marimon et al., 2006). The fungus usually penetrates through the skin but seldom could be acquired by inhalation. *S. brasiliensis* is able to be transmitted by cats and family clusters such as zoonotic outbreaks have been described so far (Brandolt et al., 2018).

The central nervous system involvement is rare and classically described as a subacute or chronic meningitis secondary to a disseminate disease. Most of cases shows an underlying medical condition leading to immunosuppression such as HIV infection or use of immune-suppressive agents (Queiroz-Telles et al., 2019). The clinical presentation is often with a slow onset of headache, confusion and symptoms of intracranial pressure increase (Kauffman et al., 2007).

The definite diagnosis is made with isolation of *Sporothrix* spp. on sterile sites such as CSF, blood or from biopsies. The fungal burden is higher in immunocompromised hosts and consequently in these patients the fungal culture in CSF more often turned positive when compared to that without disseminate disease (Moreira et al., 2015). The biochemical characteristics of CSF are comparable to that of other chronic meningitis with increased cellularity (mononuclear), increase in proteins and reduced glucose level.

The treatment of *Sporothrix* spp. meningitis is the same of the disseminate disease and is based on an induction with liposomal amB for 4–6 weeks followed by a step-down treatment with itraconazole for at least 12 months. The prosecution of a lifelong azole suppressive treatment should be considered in case of persistent immune suppression (Kauffman et al., 2007).

Dematiaceous mold (*Exserohilum rostratum*)

Dematiaceous fungi are rare cause of fungal meningitis which usually occur in immunocompetent hosts (McCarthy et al., 2014). An invasive form which can involve the central nervous system is known as phaeo-hyphomycosis. In a literature review of 101 cases approximately 50% showed an underlying medical condition leading to immunosuppression and meningitis was the clinical presentation in 9% of cases (Revankar et al., 2004).

Among dematiaceous fungi, *Exserohilum rostratum* emerged as a cause of fungal meningitis in 2012 when the Centers for Disease Control and Prevention reported a large outbreak of infections in patients who received injections, primarily epidural, of methylprednisolone acetate (Pettit et al., 2012). The investigations performed highlighted how the infection derived from the contamination of the product produced from a single company during the manufacturing production (Centers for Disease Control and Prevention (CDC), 2012). The outbreak comprehended 753 patients accounting from 64 (8%) death related to the infection by *E. rostratum*. Moreover, almost all patients with spinal or paraspinal involvement showed persistent disability at 12 months of follow-up (Malani et al., 2020). After the injection the first manifestation was fungal meningitis with some patients developing stroke and subsequently a wide range of other syndromes caused by the IFD. The symptoms reported in those who developed meningitis were headache in 91% of cases, fever in 38%, and decreased cognitive function in 28% of case which was classified as persistent at 12 months as mild-moderate in 11% of patients. Patients who developed meningitis with or without stroke were those at higher risk of death with an eightfold higher risk of death when compared to the spinal/paraspinal (hazard ratio, 7.62; 95% CI, 3.17–18.37) (Malani et al., 2020).

The initial antifungal treatments used was voriconazole at a dosage of 6 mg/kg the first day every 12 h followed by 4 mg/kg daily every 12 h, in case of refractory disease in can be used in combination with liposomal amB 5 mg/kg daily. Moreover, a prompt neurosurgical assessment is warranted with appropriate surgical debridement in case of spinal or paraspinal involvement (McCarthy et al., 2014). The treatment duration is prolonged (usually of 4 (2–9) months) and the relapse of the infection is not infrequent after a median of 3 (1–14) months from treatment interruption (Malani et al., 2020).

Candidiasis

Introduction

Candida species is the most common causative agent of intra-uterine infections involving the placenta, umbilical cord, and fetus. Over 100 case reports and short case series have been published since the first case of chorioamnionitis caused by *Candida albicans* that resulted in preterm birth and neonatal death in 1958 (Benirschke and Raphael, 1958). As the prevalence of this disease is very rare in the general population, the largest study series comprised only 32 cases (Qureshi et al., 1998). Therefore, clinical manifestation is not well understood. According to the largest literature review, intra-uterine *Candida* infection may result in stillbirth, preterm delivery, and neonatal death (Maki et al., 2017).

This topic will discuss clinical manifestations, diagnosis, and treatment of intra-uterine *Candida* infection.

Epidemiology

Candida species rarely causes intra-uterine infections that result in chorioamnionitis, funisitis, and congenital candidiasis despite the high incidence of vulvovaginal candidiasis during pregnancy (13–40%) (Kiss et al., 2004; Roberts et al., 2011; Barton et al., 2017). The published literature includes a few case reports and case series. As there is no report that assessed the prevalence of intra-uterine *Candida* infection in the general population, the actual prevalence is unclear. In the largest case series, four among approximately 10,000 placentae from 70,000 deliveries had *Candida* infection (Qureshi et al., 1998). At regional referral centers, the prevalence of *Candida* chorioamnionitis is reported to be 0.5% in the south central region of Ontario, Canada (Whyte et al., 1982), and 0.3% in the southern region of Japan (Maki et al., 2017). A review of intra-amniotic infection published in 1992 showed that the prevalence of *Candida* species isolated from the amniotic fluid obtained by transabdominal amniocentesis was 6.5% (5/773) in cases with preterm labor with intact membranes and 2.2% (4/625) in cases with preterm prelabor rupture of membranes (pPROM) (Chaim et al., 1992). Another study showed that the isolation rate of *Candida* species from the amniotic fluid was 5% and 1.2% using polymerase chain reaction (PCR) method and 3.2% and 0.6% using culture-based methods in patients with pPROM and preterm labor with intact membranes, respectively (DiGiulio et al., 2008).

Transmission

As observed with bacterial intra-uterine infection, ascending *Candida* infection from the vagina and cervix to the uterine cavity is probably the most common pathway. Therefore, the rupture of membranes is a risk factor of intra-uterine *Candida* infection. The incidence of *Candida* species isolation from the amniotic fluid of patients with pPROM is higher than that from the amniotic fluid of patients with intact membranes (DiGiulio et al., 2008). A previous study reported that 25% cases were associated with pPROM

(Maki et al., 2017). Interestingly, an in vitro study using human fetal membranes showed that *C. albicans*, but not *C. glabrata*, *C. pseudotropicalis*, *C. guilliermondii*, and *C. tropicalis*, penetrates the fetal membrane, accompanied by the degeneration of the structure of the membrane epithelium (Gürkan et al., 1994). Why *Candida* species rarely causes intra-uterine infection is less understood, although its colonization in the vagina is very common (Kiss et al., 2004; Roberts et al., 2011; Barton et al., 2017). A previous review failed to show the association between vaginal *Candida* colonization and intra-uterine *Candida* infection, owing to the lack of information on vaginal *Candida* colonization in most cases (Maki et al., 2017). A possible case of the inoculation of the maternal skin flora into the uterine cavity by transabdominal amniocentesis has also been reported (Rode et al., 2000).

Microbiology

A case control study involving 18 cases with *Candida* chorioamnionitis reported *C. albicans* in 15 cases, and the remaining three cases were one each of *C. parapsilosis*, *C. tropicalis*, and *C. stellatoidea* (Whyte et al., 1982). *C. albicans* is a predominant species accounting for 71.3% cases (72/101), followed by *C. glabrata* (21.7% [21/101]) (Maki et al., 2017). Recently, there has been an increase in case reports of *C. glabrata* infection associated with in vitro fertilization (IVF). There are a few reports of cases with other *Candida* species infection, including *C. tropicalis* ($n = 3$) (Nichols et al., 1995; Barth et al., 2002; Canpolat et al., 2011), *C. lusitanae* ($n = 2$) (DiLorenzo et al., 1997; Huang et al., 2012), *C. parapsilosis* ($n = 2$) (Waguespack-LaBiche et al., 1999; Krallis et al., 2006), *C. famata* ($n = 1$) (Maki et al., 2017), and *C. kefyr* ($n = 1$) (Pineda et al., 2012). Coinfection with *C. albicans* and *C. parapsilosis* has also been reported (Waguespack-LaBiche et al., 1999; Krallis et al., 2006), including a case of twin pregnancy where blood cultures were positive for *C. albicans* in one of the two twin infants and *C. parapsilosis* in another twin (Krallis et al., 2006).

Risk factors

Several studies suggest foreign bodies in the uterus to be associated with intra-uterine *Candida* infection. Intra-uterine device (IUD) is a well-known risk factor. A case series revealed 3 of 32 cases of *Candida* funisitis to carry IUD (Qureshi et al., 1998). Further, a case control study showed that 8 of 18 cases with *Candida* chorioamnionitis had IUD (Whyte et al., 1982). In addition, a review on fetal *Candida* infection found 17 of 54 cases to be associated with IUD and that the presence of IUD was associated with systemic (heart, brain, liver, gastrointestinal, and lung) fetal infection (Roqué et al., 1999). In a review of 123 cases, 21% *Candida* chorioamnionitis cases had IUD (Maki et al., 2017). Statistical studies strengthened the association between IUD and intra-uterine *Candida* infection. A retrospective cohort study involving 196 cases with IUD during pregnancy concluded the presence of IUD as a risk factor for late miscarriage, preterm delivery, vaginal bleeding, histological chorioamnionitis, clinical chorioamnionitis, and placental abruption. Furthermore, the prevalence of intra-amniotic infection caused by *Candida* species was higher in pregnant women with IUD than in those without IUD (31.1% vs 6.3%, $P < 0.001$) (Kim et al., 2010). Another retrospective study showed that pregnancies with IUD were associated with higher prevalence of *Candida* invasion of the amniotic cavity than those without IUD (28% vs 3%, $P < 0.01$) (DiGiulio et al., 2010). The mechanism of transmission of *Candida* species to the pregnant uterine cavity with IUD is not known, but some theories are proposed. The IUD string can serve as a route of fungal transmission from the vagina to the uterine cavity (Delprado et al., 1982). Contamination with *Candida* species may occur at the time of IUD insertion (Schweid and Hopkins, 1968). An in vitro study showed that *C. albicans* isolated from vaginal discharge of patients with vulvovaginal candidiasis strongly adhered to all parts of IUD and produced biofilm (Chassot et al., 2008).

Cervical cerclage is also reported as a risk factor for intra-uterine *Candida* infection. *Candida* infections associated with cervical cerclage were reported in 2 of 32 cases (Qureshi et al., 1998) and 5 of 18 cases (Whyte et al., 1982) in previous studies. Another study reported that 8 of 123 cases (6.5%) had cervical cerclage (Maki et al., 2017). However, there is no statistical evidence supporting this information.

In recent years, there has been an increase in case reports on intra-uterine *C. glabrata* infection following IVF. A literature review of 20 cases of intra-uterine *C. glabrata* infection showed that 13 of them were associated with IVF (Ganer Herman et al., 2015). Cases of intra-uterine infection caused by other *Candida* species, including *C. albicans*, *C. parapsilosis*, *C. kefyr*, and *C. famata*, have also been reported. In a review on 123 cases, 20% were related to IVF (Maki et al., 2017). Any steps in the process of IVF may contaminate the fertilized embryo or introduce *Candida* species into the uterine cavity.

Clinical manifestations

Maternal symptoms are unspecific. Preterm labor with an intact membrane is the most common symptom (42%), and pPROM and cervical dilatation without uterine contraction are also frequent (25% and 9%, respectively). Fever was reported in only 13% cases (Maki et al., 2017).

Diagnosis

Isolation of *Candida* species from the amniotic fluid or pathological findings of the presence of fungal cells with inflammation in the placenta, fetal membrane, umbilical cord, and/or fetus is the gold standard for diagnosis of intra-uterine *Candida* infection. A limitation of pathological findings is that these are available only after delivery. Therefore, amniotic fluid test through transabdominal amniocentesis is imperative for antenatal diagnosis. According to a previous study, antenatal treatment was attempted in

13 cases. All these cases were diagnosed using amniotic fluid culture obtained by transabdominal amniocentesis (Maki et al., 2017). Transvaginal sampling of amniotic fluid should be avoided, owing to the risk of vaginal colonization with *Candida* species.

Standard culture method is commonly used in clinical practice, whereas PCR is used in the research field. A retrospective study showed the combination of PCR and culture method achieved higher detection rate of *Candida* species than culture method alone (5% vs 3.2%) (DiGiulio et al., 2010). Beta-glucan, a constituent of the cell wall of fungi, test in the amniotic fluid can be useful for rapid diagnosis (Pacora et al., 2019).

Pathological findings in the placenta, umbilical cord, and fetus

Chorioamnionitis and funisitis are common like bacterial intra-uterine infection. Macroscopically, yellow-white nodules on the umbilical cord are typically observed in intra-uterine *C. albicans* infections (Fig. 1). These nodules are formed by subamniotic abscesses with fungal cells (Qureshi et al., 1998). Grocott and periodic acid-Schiff staining can highlight yeasts with pseudohyphae in the fetal membrane and umbilical cord (Fig. 2). The nodules may not be clearly visible in *C. glabrata* infection (Ibara et al., 2004; Matsuzawa et al., 2005). Although the typical yellow-white nodules may be absent, the infiltration of yeast-like organisms without pseudohyphae consistent with the morphology of *C. glabrata* can be observed in the fetal membrane upon Grocott and periodic acid-Schiff staining in cases with *C. glabrata* infection (Ibara et al., 2004; Özer et al., 2013; Sfameni et al., 1997; Jackel and Lai, 2013; Freydiere et al., 2005).

There are several reports on fetal autopsy of stillbirth cases. Skin rash is commonly observed on gross examination. Microscopic examination has revealed fungal cells on the epithelial surface and hair follicles with inflammatory cells (Buchanan et al., 1979; Donders et al., 1997; Spaun and Klünder, 1986). Fungal invasion into the respiratory tract and lungs along with inflammation is the most frequent feature, suggesting that the direct aspiration of *Candida* species in the amniotic fluid is the main cause of fetal infection (Nichols et al., 1995; Huang et al., 2012; Schweid and Hopkins, 1968; Sfameni et al., 1997; Buchanan et al., 1979; Meizoso et al., 2008; Chaim et al., 1993; Bittencourt et al., 1984; Ho and Aterman, 1970; Lee and Lo, 2011). On the other hand, *Candida* species can be ingested into the gastrointestinal tract. Fungi are often seen in the stomach and intestine, but the bowel wall is usually free of fungus and inflammation (Huang et al., 2012; Ibara et al., 2004; Meizoso et al., 2008; Bittencourt et al., 1984; Ho and Aterman, 1970; Lee and Lo, 2011; Rivasi et al., 1998). In cases with severe infection, dissemination of fungi is observed in multiple organs, including the kidney, liver, spleen, and brain (Engelhart et al., 1998; Levin et al., 1978).

Treatment

Prompt delivery and treatment with an antifungal agent individually for the mother and the infant is preferable because no optimal antenatal treatment for intra-uterine *Candida* infection is yet established, although the immaturity of the infant is often crucial. Various antenatal treatment regimens have been tested. Amphotericin B offers some advantages for antenatal treatment, as it crosses the placenta, does not exert teratogenic effects or fetotoxicity (Briggs and Freeman, 2017), and is generally effective against *C. glabrata*, the second most prevalent species of intra-uterine *Candida* infection. Amphotericin B is recommended as the first-line treatment against invasive candidiasis in pregnant women and neonates (Pappas et al., 2016). A case of successful intravenous amphotericin B treatment was reported that resulted in pregnancy extension by 4 weeks and delivery of twin infants with no signs of chorioamnionitis or funisitis (Tan et al., 2015). However, there are some cases of stillbirth after intravenous amphotericin B treatment (Jackel and Lai, 2013; Garcia-Flores et al., 2016; Akhanoba et al., 2014). Transcervical intra-amniotic administration of amphotericin B for a case with pPROM caused by intra-uterine *C. albicans* infection has been reported. Intra-uterine *C. albicans* infection was confirmed by amniotic fluid culture obtained by transabdominal amniocentesis. Amphotericin B 2 mg in 1000 mL of normal saline was infused into the uterine cavity via the transcervical catheter at first time, and the dose was subsequently increased to 10 mg. After 5 days of daily infusion, culture of the amniotic fluid turned negative for *C. albicans* and spontaneous labor occurred on day 7 of treatment (Shalev et al., 1994).

Fig. 1 Yellow-white nodules on the umbilical cord.

Fig. 2 Subamniotic abscesses with fungal cells on the umbilical cord (PAS stain).

Fluconazole is the most popular agent in case reports (Ganer Herman et al., 2015; Arai et al., 2002; Crawford et al., 2006; Poliquin et al., 2015; Bean et al., 2013), although whether it crosses the placenta is unknown (Briggs and Freeman, 2017). Further, it exerts less activity against *C. glabrata*. Weekly intra-amniotic administration of 40–100 mg fluconazole combined with oral administration succeeded in pregnancy extension for 6–8 weeks and delivery of infants without congenital candidiasis (Bean et al., 2013). Given the potential risk of teratogenic effects on the fetus, careful patient selection is necessary (Briggs and Freeman, 2017; Zhu et al., 2020). The efficacy and safety of micafungin is unclear. The characteristics of micafungin, such as high molecular weight, low lipid solubility, and very high protein-binding ability, suggest the limitation of its transfer to the fetus (Briggs and Freeman, 2017). Intravenous micafungin administration was attempted in one case that failed to eradicate *C. glabrata* from the amniotic fluid but extended pregnancy for 10 days and led to live infant delivery (Alfei et al., 2014).

Prognosis

In a case series of 32 cases, 24 had premature delivery and 7 cases were delivered within 26 weeks. All fetuses and neonates died perinatally. There was no perinatal death among the remaining 25 cases born after 26 weeks, although 4 of these 25 cases had congenital candidiasis (Qureshi et al., 1998). In a literature review of 123 cases, 27% of all singleton cases were delivered before 22 weeks and 60% were delivered between 22 and 36 weeks. Almost 30% singletons born after 22 weeks died. As the description of the clinical features is heterogeneous among the reports, whether the cause of death is congenital candidiasis is unclear. The authors concluded that immaturity and severe fetal inflammation may lead to high mortality rate (Maki et al., 2017).

Less common fungal infections

Placental and fetal infections with fungi other than *Candida* species are extremely rare. Given the rarity of such infections, clinical information is limited. Several cases of neonatal fungal infections have been reported. These cases may include vertical transmission in utero, aspiration or swallowing of infected vaginal secretions during delivery, and acquisition after delivery. As this chapter focuses on placental and fetal infections, we discuss only cases with placental infection, vertical transmission in utero confirmed by fetal autopsy, and early neonatal infection accompanied with placental lesions.

Pneumocystis infection

Pregnant women are at increased risk of colonization with *Pneumocystis jirovecii*. The positive rate of *P. jirovecii* DNA in the nasal swabs of healthy pregnant women was higher than that from samples of nonpregnant controls (15% vs 0%) (Vargas et al., 2003). *P. jirovecii* pneumonia was the most common cause of death in pregnant women with human immunodeficiency virus (HIV) infection in the United States in 1980s (Koonin et al., 1989). A literature review of *P. jirovecii* pneumonia in HIV-infected pregnant women found 22 cases and reported a very low fetal/neonatal survival rate (10/22, 54.5%). There is only one report describing fetal infection with *P. jirovecii* where an HIV-infected pregnant woman was diagnosed with *P. jirovecii* pneumonia at 24 weeks of gestation. Despite the treatment, the pregnancy resulted in stillbirth and the patient died after delivery. Autopsy of the fetus revealed *P. jirovecii* in the interalveolar macrophages in the fetal lung without any signs of interstitial pneumonitis. *P. jirovecii* was also found in placental sections (Mortier et al., 1995), although there is a controversial opinion (Hughes, 1995). There are a few cases of congenital pneumocystic pneumonia reported before the acquired immunodeficiency syndrome (AIDS) epidemic

(Pavlica, 1962; Bazaz et al., 1970). A study detected *P. jirovecii* DNA from the placenta and lungs of aborted fetuses delivered from immunocompetent women (Montes-Cano et al., 2009). These findings suggest the possibility of maternal-fetal transmission of *P. jirovecii*.

Blastomycosis

Blastomycosis is caused by *Blastomyces dermatitidis*, a dimorphic environmental fungus. Whether it is transmitted from the mother to the fetus is yet unknown. In a literature review of 23 cases of blastomycosis during pregnancy, two neonates died from blastomycosis (Baker et al., 2017). Symptoms were presented at 18 days and 3 weeks of age. Both neonates were not examined at birth and were asymptomatic until then. The placenta was not evaluated (Maxson et al., 1992; Watts et al., 1983). Therefore, the route and timing of infection are unclear (Baker et al., 2017). There is one case of placental blastomycosis confirmed by pathology that demonstrated dimorphic blastomycosis spores on both maternal and fetal sides. Culture of placenta was positive for *B. dermatitidis*, but all cultures of the fetus were negative (MacDonald and Alguire, 1990).

Cryptococcosis

Cryptococcosis, which is caused by *Cryptococcus neoformans*, is an opportunistic infection in immunocompromised patients. There are four case reports of placental cryptococcosis diagnosed by placental pathology demonstrating mucin-positive yeasts in the intervillous space (Kida et al., 1989; Molnar-Nadasdy et al., 1994; Darko et al., 2009; Patel et al., 2012) and chorionic villi (Darko et al., 2009; Patel et al., 2012). There is another case of numerous cryptococcus accompanied with a granulomatous response found in aborted specimen from a HIV-positive mother (Rahimi et al., 2009). These reports suggest that *Cryptococcus* can invade the placenta. Among the four cases of placental cryptococcosis, one neonate had congenital cryptococcosis (Patel et al., 2012). The mother was HIV positive and her blood and cerebrospinal fluid cultures were positive for *C. neoformans* at 25 weeks of gestation. Intravenous amphotericin B treatment improved her symptoms. The neonate was born by caesarean section at 28 weeks of gestation because the mother developed preeclampsia. The neonate had positive serum cryptococcal antigen, but the cerebrospinal fluid analysis was normal. The neonate was treated with amphotericin B followed by fluconazole, which resolved antigenemia.

Coccidioidomycosis

Coccidioidomycosis is caused by *Coccidioides immitis* or *C. posadasii*. Pregnancy is a risk factor for coccidioidomycosis. In particular, severe primary and disseminated coccidioidomycosis may develop in third trimester and after delivery (Peterson et al., 1993; Crum and Ballon-Landa, 2006; Bercovitch et al., 2011). There is no evidence of confirmed maternal-fetal transmission of *Coccidioides* species in utero. However, several reports have shown the placental involvement. A study reported over 15 cases with placental lesions of coccidioidomycosis showed that *Coccidioides* spherules containing endospores localized by necrosis and deposits of fibrin with acute and/or chronic granulomatous inflammation in the placenta (Labuschagne et al., 2016). The fetuses/neonates were not infected with *Coccidioides* species even in these cases. Fibrin deposition is related to the pathogenesis of coccidioidomycosis. It may help to inhibit vascular access and prevent transmission to the fetus (Labuschagne et al., 2016). There are several reports of neonatal coccidioidomycosis. These cases may be infected by aspiration of vaginal secretions at the time of delivery (Bercovitch et al., 2011).

Histoplasmosis

Histoplasmosis is caused by a dimorphic fungus, *Histoplasma capsulatum*. The first case of placental and congenital histoplasmosis was reported in 2004. The report comprised three cases of histoplasmosis during pregnancy. The mother developed acute respiratory distress after cholecystectomy at 25 weeks of gestation. The bronchoalveolar lavage and blood culture were positive for *H. capsulatum*. The neonate was delivered by emergency cesarean section. *H. capsulatum* was detected in the blood, cerebrospinal fluid, and peritoneal fluid culture of the neonate. The neonate was discharged after 103 days of amphotericin B treatment. Placental histology showed clusters of yeasts in the villi and trophoblast. Morphological features in Grocott-Gomori methenamine-silver staining and Periodic acid-Schiff staining were consistent with those of *H. capsulatum*. The other two cases had no evidence of placental histoplasmosis by pathological examination. One fetus died from maternal ketoacidosis, while the other had no symptoms and abnormal examinations (Whitt et al., 2004). Another congenital histoplasmosis has been reported. The neonate was born at 36 weeks of gestation from the mother with disseminated histoplasmosis. The mother had severe inflammatory bowel disease and received anti-tumor necrosis factor (TNF) monoclonal antibody every 6 weeks by 32 weeks of gestation. Histoplasma antigen was detected in the umbilical cord, although the neonate was asymptomatic. Histoplasma antigen was detectable in the urine and serum at 3 weeks of age. The patient was treated with amphotericin B and itraconazole. Interestingly, histological findings of the placenta were normal, and no fungal forms were detected by Grocott-Gomori methenamine-silver staining (Carlucci et al., 2016). Histoplasmosis was also reported in another infant that developed fever and rash at 4 weeks of age and was diagnosed with disseminated histoplasmosis. HIV test was positive for both the infant and the mother. Further, the mother showed elevated urine histoplasma antigen level. The authors suspected vertical transmission (Carlucci et al., 2016). However, there is no evidence that the infant had histoplasmosis at birth, and there is no description of placental pathology.

Zygomycosis

Zygomycosis is caused by fungi of the class *Zygomycetes* consisting of the orders *Mucorales* and *Entomophthorales*. *Rhizopus*, *Mucor*, and *Lichtheimia* are the most common fungi of this group (Petrlikos et al., 2012). There are two reported cases of placental zygomycosis. In the first case, the neonate delivered vaginally had respiratory failure but no signs of infection and could recover. The mother had habit of smoking cocaine and marijuana. Placental pathology showed broad, ribbonlike, and aseptate fungal hyphae consistent with morphology of *Zygomycetes* in the chorionic plate and the umbilical vessels without inflammation. Culture was not performed (Kambham et al., 1998). Another case involved a stillborn case at term. The mother had no comorbidity. Numeral fungal hyphae consistent with the morphology of *Zygomycetes* were noted in the villi, membranes, and umbilical cord without inflammatory cells. The dead fetus had no signs of infection upon microscopic examination (Marcorelles et al., 2005). As both cases showed no inflammation in the placenta or signs of infection in the fetus or neonate, the clinical importance of placental zygomycetes is unclear.

Oral health

The attention to oral health dates back to thousands of years ago, with written evidence of a dentistry job recovered from a 4600-year-old Egyptian tomb and the use of basic dental practices dating back to the Ancient Greeks (Blackburn, 1977). Throughout the centuries, both the field of dentistry and the importance of oral health experienced a constant growth, reaching new heights with the discovery of the oral microbiome and its effects on multiple diseases and body niches. A clear example of the importance of oral health can be given by its impact on human health and the ensuing economic burden. Despite the difficulties, research efforts from the past two and a half decades have yielded some of the first comprehensive studies based on Big Data science regarding the impact of oral diseases in global health, as depicted in the first global burden of disease (GBD) epidemiological reports (Marcenes et al., 2013; Kassebaum et al., 2015). These reports showed that at least 3.5 billion people are affected worldwide by some of the most common oral diseases (untreated dental caries, severe periodontitis, and edentulism) (Kassebaum et al., 2017). According to the newest GBD report from 2019, the morbidity and mortality of oral disorders (including lip and/or oral cancer) accounted for a global median loss of 28,641,313.63 years of healthy life due to early death and disability, known as Disability Adjusted Life Years (DALYs) (IHME GBD, 2019). This means that oral disorders represent 1.13% of the total global DALYs for 2019, a 1.82-fold increase compared to data from 1990. This last number is worthy of notice since it depicts a result of what is regarded as the “Global Epidemiological Transition” (The Lancet, 2016). This concept aims to describe how the health problems transition in economically developed states and result in the prevalence of non-communicable and chronic diseases, such as oral disorders, in comparison to communicable diseases (which have decreased their impact on morbidity and mortality from 31.7% in 1990 to 15.59% in 2019, a 2.03-fold decrease) (IHME GBD, 2019). Moreover, it is estimated that the economic burden to treat dental diseases (including periodontal disease) is approximately USD\$298 billion per year, which is equivalent to an average of 4.6% of the global health expenditure per year (Listl et al., 2015).

Oral microbiome

The term “microbiome” describes the collection of commensal, symbiotic, and pathogenic microorganisms inhabiting our bodies, with an untold and underestimated potential for human health and diseases (Lederberg and McCray, 2001). As there are almost as many microbiome communities as there are body niches suited to their growth, there are several different types of human microbiomes, with potentially more to discover (Scotti et al., 2017). One of the most important microbiomes is the oral one, and the discovery of some of its members coincides with the discovery of bacteria by Antony van Leeuwenhoek in 1676, with a self-constructed microscope (Yamashita and Takeshita, 2017). The human oral microbiome comprises all the microorganisms that are found on or in the human oral cavity and its contiguous extensions, stopping at the distal esophagus (Dewhirst et al., 2010). The

*These authors contributed equally to this work.

oral cavity is the gatekeeper of the human body and it is the second largest microbial habitat in humans, colonized by one of the most diverse communities of microbes, including viruses, bacteria, fungi, archaea, and protozoa (Huttenhower et al., 2012; Li et al., 2012). The mouth is, in fact, uniquely suited to microorganisms, being a warm and moist environment perfect for the growth of different kinds of microbes (Van'T Hof et al., 2014) and providing non-shedding surfaces that can help microbial colonization, development of thick biofilms, and microbial persistence (Marsh and Devine, 2011). However, as humans evolved countermeasures against oral bacterial colonization, the mouth can also be hostile to microbial life, resulting in only a subset of microbes entering the oral cavity being able to survive and colonize this niche (Marsh and Devine, 2011) on few sites such as dental surfaces, cheek, hard palate, tongue, and saliva. The microorganisms differ significantly on these different oral habitats, which show distinct microbial profiles (Papaioannou et al., 2009). Interestingly, in healthy individuals, the dental samples from different surfaces display the highest diversity (Zaura et al., 2009). According to the Human Oral Microbiome Database (HOMD), a total of 619 taxa has been identified in the human oral cavity, only 65,6% of which have been cultured (Aas et al., 2005; Dewhirst et al., 2010). However, most of the oral microbiome is still under investigation, with some bacterial species not being officially named, or even not cultivated (Wilson, 2005), as of yet resulting in a compendium of only 700 bacterial species (Deo and Deshmukh, 2019).

The oral microbiome forms an ecosystem, which is responsible for maintaining oral homeostasis, protecting the oral cavity health and preventing disease development (Luftig, 2009; Welch et al., 2016; Deo and Deshmukh, 2019). However, when the ecosystem is imbalanced or ecological shifts occur in the microbiome, pathogens can seize the opportunity to cause infection and diseases (Avila et al., 2009; Deo and Deshmukh, 2019). These changes in the microbiome composition, collectively known as dysbiosis, can lead to oral diseases such as oral cancer (Zhao et al., 2017), and systemic diseases such as cardiovascular diseases (Beck and Offenbacher, 2005), metabolic diseases, and autoimmune disorders (Cho and Blaser, 2012; Muszer et al., 2015; Levy et al., 2017). The definition of dysbiosis as an imbalance in the microbiome profile and a change from its healthy, eubiotic, stage props the question of the existence of a common healthy microbiome. Although oral microbiomes in different people show some diversity, the major portion of the oral microbial community was found to be shared across unrelated healthy individuals (Zaura et al., 2009). This supports the concept of a core microbiome common to all individuals, albeit affected by age, unique lifestyle, genotypic differences, host genetics, and diet habits (Zarco et al., 2012; Deo and Deshmukh, 2019). At the time of birth, the human oral cavity represents an essentially microbe-free niche that becomes colonized within hours by maternal bacteria (Dominguez-Bello et al., 2010). With the host's growth, the oral microbiome changes and the number and diversity of periodontal pathogens in it increases, showing a pattern of colonization in children similar to that previously found in adults, resulting in higher susceptibility to oral diseases and a gradual maturation of the oral microbiota (Papaioannou et al., 2009; Lira et al., 2018). The juvenile population, instead, was observed to present a significant increase in bacterial species compared to adults (Lira et al., 2018).

The different European, African, Asian, and American populations present different oral microbial compositions. For instance, the saliva microbiomes of Alaskans, Germans, and Africans displayed a significant degree of diversity between and within individuals (Li et al., 2014a). Furthermore, two Caucasian and African American populations from the United States, which shared common food, nutritional and lifestyle heritage demonstrated significant microbial differences in the oral cavity, showing that host genetics is also very important for oral microbiome composition (Mason et al., 2013). Nonetheless, focusing on the evolution and changing ecology of the human oral microbiome, the core microbiome of primarily biofilm structural taxa has been maintained throughout African hominid evolution, but strain-level differences are also indicated within the core taxa, according to reconstructions of oral metagenomes from up to 100 thousand year ago (Yates et al., 2021).

Main oral diseases

A dysbiotic oral microbiome, or a specific pathogenic member of the oral microflora, can lead to the development of oral diseases, which can vary greatly from oral infections to cancer. With a few exceptions, in fact, most oral ailments are microbial in nature, or have oral bacteria playing a role in their etiopathogenesis. This, coupled with the knowledge of the staggering economic burden caused by oral diseases, shows the importance of studies trying to uncover the molecular mechanisms and the microbial actors underlying the etiology of these diseases. The most important oral disorders, whose pathogenesis involves oral bacteria are tooth decay, oral cancer, periodontal diseases, and noma.

Tooth decay

Tooth decay, also known as dental caries, is one of the most common chronic diseases and the major cause for tooth loss worldwide. Caries is the deterioration of dental hard structures through acidic by-products of bacterial carbohydrate fermentation in a process called demineralization (Selwitz et al., 2007). It affects the majority of adults and 60–90% of school children, varying with age, geographic location, food habits, sex, and socio-economic status. Risk factors for the development of tooth decay include an insufficient fluoride exposure, high amounts of cariogenic bacteria, recession of the gingiva, as well as genetic and immunological factors and previous caries experience. The symptoms of tooth decay include toothache and sensitivity, especially when eating or drinking something cold, hot, or sweet, as well as a dark-brown or white staining of the tooth surface, visible pits or holes in teeth and bad breath, while complications may include tooth loss, discoloration, Ludwig angina and Cavernous sinus thrombosis, which may even be lethal (Yadav and Prakash, 2016). The most common diagnostic method is the visual examination of the teeth and may include the use of a dental probe (Selwitz et al., 2007). Caries is initiated by changes in the bacterial composition of the dental biofilm (plaque). With the thickening of the biofilm and the increased production of exopolysaccharides, the saliva is unable to

buffer the decrease in pH caused by the bacteria and cannot therefore enhance the re-mineralization of the tooth structure, leading to disease progression (Baker and Edlund, 2019). Disease evolution is slow in most patients since it can be halted at any moment for prolonged periods of time. Several bacterial genera are involved in tooth decay, most of which are facultative or strict anaerobes. The main species associated with dental caries are *Streptococcus mutans* and other mutans streptococci, lactobacilli, *Bifidobacterium* spp., and *Actinomyces* spp. (Selwitz et al., 2007). Cariogenic biofilms change their bacterial composition over time, depending on disease progression and depth of the lesions (Yadav and Prakash, 2016; Lamont et al., 2018). The interplay between acidogenic bacteria and species able to tolerate such a decrease in pH is key for the establishment of caries and its progression. In particular, *S. mutans* has been found to play a major role in this transition. The bacterium, in fact, is able to decrease surrounding pH, resulting in toxicity for certain microorganisms and a shift in the types of species growing on the tooth. Therefore, *S. mutans* can be seen as a keystone species involved in the caries biofilm and matrix formation (Lamont et al., 2018). Mutans streptococci and other cariogenic bacteria may be acquired via vertical and horizontal transmission routes, for example from a mother to her child. Under healthy conditions and with a diet low in fermentable carbohydrates certain bacterial commensals, especially Mitis streptococci, are able to outcompete cariogenic species and keep homeostasis. Apart from bacteria, *Candida albicans* has also been found to initiate severe caries *in vivo* when associated with cariogenic bacteria, especially *Streptococcus mutans* (Selwitz et al., 2007; Lamont et al., 2018).

The progression of tooth decay is influenced by factors such as lifestyle, including (dietary) fluoride exposure, oral hygiene, the consumption of fermentable carbohydrates, as well as salivary composition and flow (Yadav and Prakash, 2016; Baker and Edlund, 2019). Caries can cause cavitation in the crown or the root of the tooth (coronal and root caries). It may affect the enamel (the outer layer of the crown), the cementum (the outer layer of the root), or the dentin (lying below cementum and enamel) and may lead to dentin exposure (Selwitz et al., 2007).

Management of caries in most countries mainly involves restorative treatment, regardless of its limitations and tendency to create the need for further treatment. Restorations usually have a short durability and caries may form around the reconstructed areas. Relapse occurs in 40% of all cases after the first year (Alazmah, 2017). Preventive care is therefore increasingly being applied due to its high effectiveness, especially in Scandinavian countries (Mjör and Toffenetti, 2000; Selwitz et al., 2007). The prevention of tooth decay involves lifestyle and nutritional changes such as the improvement of oral hygiene and health education programs, as well as the removal of biofilm (plaque) and the application of fluoride, and the use of sealants for tooth protection (Bader et al., 2001; Selwitz et al., 2007). According to a 2015 Cochrane study, one of the most effective ways to prevent caries has been found to be the self-application of fluoride toothpaste (Marinho et al., 2015).

Early childhood caries is a serious and destructive form of tooth decay affecting the primary teeth of young children worldwide, with a higher incidence in families with poor economic conditions (Çolak et al., 2013). It may start at the eruption of primary teeth and occurs up to the age of 5. With its high incidence amongst childhood chronic conditions, early childhood caries highly influences the child's well-being by causing bacteremia, inflammation, tooth loss, and pain if left untreated. It may also lead to a decrease in confidence of the child, as well as speech disorders and growth alterations (Alazmah, 2017). Affected individuals have a much greater probability of developing caries in adulthood (Çolak et al., 2013). Early childhood caries initiates as white spots close to the gingival margin, usually on anterior teeth and maxillary molars, and may destroy the crown if it remains untreated. In severe cases, maxillary teeth may be completely destroyed and the disease might spread to the lower teeth (Selwitz et al., 2007). An important risk factor apart from socioeconomic status and dietary sugar intake are feeding practices such as the improper use of baby bottles. The prolonged exposure to lactose due to a longer bedtime use of bottles, in fact, represents a major risk factor for early childhood caries. Tooth extraction is the primary way of treating early childhood caries, which may however result in further orthodontic problems, especially upon removal of molars (Çolak et al., 2013).

Oral cancer

The term oral cancer refers to several malignant oral tumors, 90% of which are oral squamous cell carcinoma (OSCC), the most common oral carcinoma, which develops from the mucosal lining of the oral cavity including the anterior part of the tongue (Bagan et al., 2010). Approximately, 450,000 individuals are diagnosed with oral cancer worldwide every year, specifically with a 1.7% incidence in men and a 0.71% incidence in women. Notably, the five-year survival rate is only 50% (Marsh et al., 2011), mainly due to the poor prognosis in the early stages. Furthermore, studies have shown individuals at high risk for developing recurrent oral cancer after survival of the first oral carcinoma (Alfano and Horowitz, 2001). The epidemiological studies in the past have established certain risk factors for cancer, including diet, tobacco use, age, genetic factors, inflammation, and viral infections (Perera et al., 2016). OSCC is of multifactor origin, where several factors act either individually or in combination to lead to pathogenesis. The chief risk factors of OSCC are smoking (with or without tobacco) and alcohol consumption, which accounts for a risk of 75% for the population to develop oral cancer (Markopoulos, 2012). Additionally, viral (human papillomavirus) infections are another major risk factor for OSCC, leading to increased incidence of cancer in the younger population and among female non-smokers (Bleyer, 2009). Surprisingly, these successful studies led to believe that there was no room left for any other causative agent, such as bacteria, to be instrumental in causing cancer development. However, studies in the 1990s established *Helicobacter pylori* to be the first bacterial species to be associated with gastric cancer and, since then, supporting research has linked microbial communities in the oral cavity with various types of cancers. Two oral bacteria, *P. gingivalis* and *F. nucleatum*, have also been linked to pancreatic cancer and colorectal cancer (CRC), respectively, but their connection with OSCC has been investigated more in depth. In particular, these bacteria might cause dysbiosis and dysregulated immune responses resulting in periodontal diseases and periodontitis, but they can also play a role in the pathogenesis of OSCC (Fitzsimonds et al., 2020).

Oral microbes can cause oral oncogenesis via several mechanisms, including inhibition of apoptosis, induced cell growth, host cell invasion, provoked inflammatory responses and production of carcinogens. Dysregulated inflammation is a key factor for modulating a tumor microenvironment. Both oral pathogens *P. gingivalis* and *F. nucleatum* survive intracellularly within epithelial cells and their persistence causes systemic spread of the disease and disrupts the immune functions (Han and Wang, 2013). A study, in fact, showed *F. nucleatum* recruiting tumor-infiltrating immune cells for the progression of CRC in an Apc^{Min/+} murine model (Kostic et al., 2013). In contrast, *P. gingivalis* can elicit both pro- and anti-inflammatory responses, thereby disrupting immune functions in the oral cavity (Lamont and Jenkinson, 1998; Takeuchi et al., 2013). However, both *P. gingivalis* and *F. nucleatum* impinge upon several aspects of epithelial cell signaling that have relevance to cancer progression.

Apoptosis inhibition

Studies have shown *P. gingivalis* to inhibit apoptosis in primary gingival epithelial cells (GECs) (Nakhjiri et al., 2001). This periodontal organism stimulates the JAK1/STAT3 and PI3K/Akt signaling pathway, which regulates pathways associated with mitochondrial apoptosis (Yilmaz et al., 2004; Mao et al., 2007). In the mitochondria, reduced release of cytochrome c is induced due to decreased activity of BAD (BCL-2-associated death promoter, proapoptotic) causing an elevated expression of BCL2 (antiapoptotic) (Yao et al., 2010). This affects the downstream genes where caspase-9 and -3 are blocked (Mao et al., 2007; Yao et al., 2010). Additionally, *P. gingivalis* induces microRNA-203 in GECs, which results in the activation of STAT3 (signal transducer and activator of transcription 3), thus further leading to inhibition of apoptosis (Moffatt and Lamont, 2011). *P. gingivalis* is also known to secrete a nucleoside diphosphate kinase (NDK), which also inhibits ATP-dependent apoptosis in gingival epithelial cells (Yilmaz et al., 2008). A study in a murine model showed that co-infection with *P. gingivalis* and *F. nucleatum* leads to oral cancer development via induction of the IL6/STAT3 pathway (Gallimidi et al., 2015).

Cell proliferation induction

P. gingivalis accelerates the growth of gingival epithelial cells through the S and G2 phases of the cell cycle. This is caused by activation of cyclins (A, D, E) and phosphorylation of CDKs (cyclin-dependent kinases) and further reduces expression of p53 (Kuboniwa et al., 2008; Pan et al., 2014). Adhesins are chief factors in inducing cell proliferation, as a mutant of *P. gingivalis* lacking the fimbrial gene *fimA* does not modulate CDK activity (Kuboniwa et al., 2008). Its LPS also plays a crucial role in dysregulating p53 (Whitmore and Lamont, 2014). Additionally, *P. gingivalis* also activates β -catenin, leading to a proliferation in GECs (Zhou et al., 2015). On the other hand, *F. nucleatum* infection results in the induction of kinases involved in cell growth, cell survival, and DNA repair signaling pathways (Uitto et al., 2005). *F. nucleatum* also activates the β -catenin pathway via the FadA adhesion protein, which binds to E-cadherin in colon cancer cells, thus leading to downstream activation of oncogenes, the Wnt pathway and proinflammatory responses, and subsequent cell proliferation (Rubinstein et al., 2013).

Cell invasion

Both periodontal pathogens *P. gingivalis* and *F. nucleatum* invade OSCC cells. During infection in OSCC, *P. gingivalis* increases the production of pro-matrix metalloproteinase-9 (pro-MMP-9) by activating signaling pathways (ERK1/2-ETS1, p38/HSP27, PAR/NF- κ B), and subsequently the active MMP-9 is produced after the proenzyme is cleaved by gingipains (Inaba et al., 2014, 2015). MMP-9 causes degradation of the basal membrane and extracellular matrix, which further enhances cellular invasion thereby causing the dissemination of cancer cells into blood and lymph for metastasis at systemic sites (Inaba et al., 2014). This causes *P. gingivalis* to stimulate tumor invasion in OSCC. Additionally, continuous exposure to the pathogen also induces the expression of MMP-1 and MMP-10 in OSCC, causing enhanced invasion (Ha et al., 2015). Likewise, *F. nucleatum* infection in the host epithelium upregulates the expression of MMP-13 via the activated p38 MAPK, thereby promoting cell migration (Uitto et al., 2005).

Inflammatory responses modulation

Inflammation induced by either infections or environmental stress is instrumental in different stages of cancer. The initiation of oncogenesis is mediated by ROS, RNS, and cytokines produced by the host cells thereby triggering genome instability and gene mutations that lead to proliferation, invasion, and metastasis (Perera et al., 2016). Proinflammatory cytokines cause the activation of STAT3 and NF- κ B transcription factors, which subsequently lead to a tumor-induced inflammatory environment (Grivennikov et al., 2010; Landskron et al., 2014). Chronic inflammation is the major pathway by which periodontal pathogens cause oral cancer. For instance, *F. nucleatum* induces high inflammatory levels in CRCs indicating a positive correlation to further cancer progression (Kostic et al., 2013). Moreover, *P. gingivalis* enhances the expression of B7-H1 and B7-DC receptors in OSCC, thereby contributing to inflammation (Groeger et al., 2011). B7-H1 expression, in turn, causes T-regulatory cell development, which further reduces the functioning of effector T-cells, contributing to immune disruption by oral oncogenesis. The induction of cytokines, such as IL-1, IL-8, and TNF- α due to *P. gingivalis* infection are key to oral carcinogenesis (Andrian et al., 2004). A similar inflammatory phenotype is also induced by other oral pathogens like *Streptococcus anginosus* and *Streptococcus mitis* (Yumoto et al., 2001; Narikiyo et al., 2004).

Carcinogen production

Acetaldehyde is categorized as a group I carcinogen since it causes point mutations, epithelial proliferation, and DNA adducts (Seitz et al., 1994). Certain oral bacteria like *Streptococcus salivarius*, *Streptococcus intermedius*, *S. mitis*, and oral *Candida* spp. harbor alcohol dehydrogenases, which lead to the production of acetaldehyde, causing mutations in the host (Kurkivuori et al., 2007).

Treponema denticola is also associated with OSCC, esophageal squamous cell carcinoma, as well as colorectal cancers (Landskron et al., 2014). *T. denticola*, in fact, secretes dentilisin (Fenno, 2012), which is primarily known for its proteolytic characteristics and is associated with early stages of cancer, enhanced tumor invasion, and tumor size (Listyarifah et al., 2018). Dentilisin also causes degradation of cytokines such as IL-8 and TNF α and cleaves inactive forms of MMP8 and MMP9 into their active forms, creating a proteolytic micro-environment for better cell invasion (Jo et al., 2014; Nieminen et al., 2018).

Periodontal disease

Evolution is driven by natural selection, where variable genetics and variable environments interact together, determining immunological phenotypes. Infections historically have been the major determinants of selection, favoring variability of the immune system. The major histocompatibility region (MHC) specifically, is one of the most variable genetic regions in many species (Parham, 2018) with the genes coding for T and B cell receptors (Han et al., 2014) providing variants for immune defense. It follows that different combinations of genes, environmental factors, and the exposure to pathogens may be active in different subsets of diseases. An example of multifactorial chronic inflammatory illness is periodontal disease (PD), which affects 10–15% of the human population. This disease usually shows few symptoms over many years, which are often not perceived or correctly classified by the patient. Therefore, awareness and recognition of an unhealthy periodontal condition are essential to prevent the disease's onset. A healthy periodontium is described as a state free from inflammation, and it is characterized by shallow pockets and the absence of gingival bleeding (Mariotti and Hefti, 2015).

Periodontitis can be classified as either aggressive or chronic periodontitis. The first type is related to young individuals presenting recent periodontal breakdown and unknown time lapse between the biological start and the clinical evidence of the disease. Chronic periodontitis affects adults which, in 85% of the cases, show no progression even after treatment (Lindhe et al., 1983).

A healthy periodontal ecosystem is established by the relationship between the virulence factors of periodontal pathogens and the tightly regulated immune responses of the host. Innate and adaptive cellular responses, together with the host's indigenous oral microbes, play in fact an important role in the prevention of pathogen invasions (Hajishengallis, 2015). To counteract the host immune defenses, periodontopathic bacteria (Hajishengallis, 2015) have evolved a range of mechanisms to circumvent the host immune reactions (Contreras et al., 2014). At the start of periodontitis, bacterial antigens attach to Toll-like pattern recognition receptors on the host immune cells. These receptors activate signaling transduction pathways which, in turn, trigger immune and inflammatory responses to eliminate invading pathogens. Next, the activated lymphocytes differentiate into subtypes. A prolonged inflammatory host response, however, might also introduce counter effects such as T- or B-cell dysregulation, DNA damage, cellular senescence, and oxidative stress, which then can potentially cause immunodeficiency and opportunistic infections. To control the latter, host-destructive immune reactions, regulatory T-cells, and noncoding RNA regulation serve to restrain or abrogate excessive inflammation, autoimmunity, and immunopathology (Kebschull and Papapanou, 2015).

Traditional periodontal therapy was originally focused on eliminating gingival bleeding and controlling patients' plaque. However, this goal was hard to achieve in practice, and modern treatments are more focused on reducing all the undesirable clinical symptoms. This goal can be achieved by treating the periodontal disease as an opportunistic infection and reducing the predisposing factors with a continuous assessment and supportive periodontal care. As periodontitis is a multifactorial disease, innovative approaches for its treatment consider an individual's genes, environment, and lifestyles. Thus, patients can be classified into diverse groups and customized clinical treatments can be established (Barros et al., 2016). One current sophisticated diagnostic test for periodontal disease is based on a proteomic or genomic assessment of body fluid such as saliva and gingival crevicular fluid (Taylor and Preshaw, 2016). Additionally, due to its complex multifactorial status, periodontitis' clinical forms and outcomes are a result of the individual's host inflammatory response. Accordingly, when diagnosing, treating, and managing periodontal diseases, the individual's inflammatory response must be considered (Giannobile et al., 2013). Today, personalized periodontics exploits modern technologies to allow the assessment of individual risks based on the analysis of biological responses, and other patient factors (Razzouk and Termechi, 2013).

Among the environmental factors influencing periodontal disease, tobacco, alcohol, medications, diabetes, obesity, malnutrition, and psychological stress are to be considered in personalized approaches for disease management (Sabbah et al., 2018). Tobacco has shown adverse side effects on periodontitis, which are associated with damage of periodontal ligament cells, an acceleration of the alveolar bone loss, and negative remodeling of alveolar bone during implantation and orthodontic treatment (Zhang et al., 2019b). Another recognized factor with an adverse effect on the periodontium is the use of drugs for both therapeutic and recreational purposes. The negative effects of drug (ab)use on the periodontium are well-documented and include drug-induced gingival overgrowth, increased gingival bleeding, and an altered inflammatory response (Bharti and Bansal, 2013).

Interestingly, many other systemic conditions are associated with poor periodontal health, and among them diabetes has been studied in detail (Borgnakke, 2016). The importance of prediabetes and poorly controlled diabetes on the periodontium has been explored, and periodontal treatment may assist in the management of prediabetes and poorly controlled diabetes and vice versa in the context of personalized periodontal care. Obesity has also a strong correlation with an increased risk for periodontitis. Specifically, studies analyzing the association between obesity and periodontal diseases indicate that obese individuals are more likely to have periodontal diseases, which can be more severe than in non-obese people. Diet and nutrition therefore have a strong impact on periodontal health and disease (Dommisch et al., 2018). In fact, certain micronutrients have an influence on biological functions, such as innate and adaptive immunity. Hence, in the context of personalized periodontics, an assessment of micronutrients intake is essential for the patients.

Another factor which has a strong impact on periodontal disease is stress (Sabbah et al., 2018). Frequent exposure to stressors leads to systemic effects and results in what is termed allostatic load. Therefore, the link of allostatic load and periodontal diseases is an important variable to consider in the field of personalized periodontics.

Aside from environmental factors, however, individual genetics has a considerable role in the manifestation of the disease (Michalowicz et al., 1991). PD forms or stages are also correlated to individual genetic susceptibility (Lauritano et al., 2015) and, therefore, the evaluation of genetic predisposition in the host-bacterial interaction may represent a crucial element to be considered for the disease's early detection, pathogenesis, and progression. Interestingly, transcriptome analyses on tissue samples have elucidated common pathways and molecular regulatory networks specific for distinct stages of PD (Sawle et al., 2016), and these insights may provide a new perspective on understanding PD pathogenesis as a response to plaque bacteria. Similarly to other common polygenic diseases, such as diabetes, coronary disease, or hypertension, the susceptibility to PD can be explained by the hypothesis that in the population there are some common disease-associated genetic variants or single nucleotide polymorphisms (Gibson, 2012). Genome-wide association analysis, therefore, represents an efficient means to identify the traits associated with the illness, reflecting different PD phenotypes at a genomic level (Zhang et al., 2016). In this regard, previous studies have confirmed the upregulation or downregulation of certain genes involved in inflammation or bone resorption (Kim et al., 2016). Specifically, two genetic variants have been implicated in the colonization of bacteria in biofilm (Nibali et al., 2014). The first variant is characterized by a single nucleotide polymorphism which may alter the function of genes in bacterial sensing and recognition such as receptor genes, or genes encoding binding. The second variant is represented by variations in genes that may lead to an excessive inflammatory environment in the subgingival niche, thus triggering the growth of certain biofilm bacteria. Notably, tissue breakdown leads to an excessive inflammatory response, which then feeds pathogenic bacteria orchestrating the biofilm formation (Moutsopoulos et al., 2014). Not by chance, immune responses and their pathways were found to be the most frequently enriched ones in the case of biofilm formation. For example, B-cell development, leukocyte extravasation signaling, phosphoinositide 3-kinase signaling in B lymphocytes, B-cell receptor signaling, and granulocyte adhesion and diapedesis were the most upregulated in periodontitis' gingival tissues once assessed with RNA sequencing (Kim et al., 2016). Moreover, an anticipatory upregulation or downregulation of some genes involved in inflammation or bone resorption has been confirmed (Langrish et al., 2005). For example, p38, c-Jun N-terminal kinase, and mitogen-activated protein kinase were identified as significantly upregulated in diseased tissues (Langrish et al., 2005). Also, an upregulation for chemokines, growth factors, tumor necrosis factor signaling, and cell adhesion molecules, was observed to be positively associated with the disease (Langrish et al., 2005).

Transcriptome studies also allowed scientists to identify novel molecules involved in epithelial function and barriers which appeared to be downregulated in the gingival tissues of patients affected by PD. As an example, the desmocollin 1 gene, expressed in epithelial cells and required for cell adhesion, was the gene most significantly downregulated. In addition, the expression of most keratin family genes, involved in the epithelial barrier, was significantly suppressed in diseased gingival tissue (Kim et al., 2016). Furthermore, transcriptome sequencing of gingival biopsies from chronic periodontitis patients has facilitated the identification of novel gene expression and splicing patterns. Specifically, downregulation of genes involved in the gingival or mucosal epithelial barrier may enable the easier penetration of pathogens (or their metabolites) into the connective tissue, thus leading to inflammation in the subepithelial region. It has also been noticed that molecules involved in the recruitment of neutrophils at the mucosal surface play a key role in the onset of inflammatory disease such as psoriasis, lupus erythematosus, and ulcerative colitis (Konig et al., 2015). Interleukin-17, primarily secreted by T helper 17 lymphocytes and involved in signaling in epithelial cells, for example, resulted in being upregulated in gingival tissues of periodontitis patients (Kim et al., 2016). This molecule plays a role against pathogen invasion by recruiting neutrophils but, if excessively secreted, leads to negative effects which may be related to inflammatory diseases.

Phenotypes, however, are not only determined by genetic sequences, but also by variable heritable factors which can influence gene expression with epigenetics being the emergent field of periodontology considering these heritable variations (Barros et al., 2018). In periodontitis, factors such as microbes became relevant in the evaluation of gene expression patterns. Recent modern technologies allowed analysis of the complex interactions between diseases and traits of epigenetic biomarkers, implying that they may serve to develop novel diagnostic and therapeutic agents in periodontal disease (Barros et al., 2018). Altogether, personalized periodontics offers an interesting move toward a new medical model of disease management, recognizing the individual as the principal component of complex diseases. An analysis of lifestyle, behavior, genetic factors, and how these interplay in periodontal diseases will probably become an integral part of everyday clinical practice. However, a considerable amount of work still needs to be undertaken to refine our diagnosis and treatment.

Bacteria use pathogen-associated molecular patterns and pattern recognition receptors to elicit inflammatory responses in different host cell populations (Poltorak et al., 1998). The bacterial lipopolysaccharide, for example, is a potent inflammation inducer by activating in the host the Toll-like receptor-4, a recognition receptor, which is found on the cell surfaces of macrophages or dendritic cells (Hawn et al., 2003). Other pathogen-associated molecular components, such as the bacterial cell wall or the flagellin protein of motile bacteria can be recognized by Toll-like receptor-2 and Toll-like receptor-5 on the host cell surfaces respectively and trigger inflammatory responses (L  e et al., 1986). However, as aforementioned, although bacteria in the plaque biofilm are responsible for initiating the inflammation, intrinsic host and environmental factors are then determinants in modulating the magnitude, duration, and extent of the periodontal inflammatory response (Sawle et al., 2016). The current periodontal microbiology theory proposes that infectious oral diseases are the result of a dysbiotic biofilm in the host, and 16S ribosomal RNA gene-sequencing technologies allowed the evaluation of the phylogenetic relation among oral bacteria. According to these studies, the notion emerged that bacterial diversity in subjects with PD is more consistent than in subjects with periodontal health (Maeda and Takeda, 2017), where health-associated species are not lost or replaced but are suppressed, and that PD is associated with shifts in the composition of species of the oral microbiota.

The future of periodontitis research is connected to the progress in biological sciences. Today's molecular technologies, such as real-time PCR, have already significantly enhanced our insights in the negative impact of pathogenic microbes on periodontal health (Slots, 2015). In particular, real-time PCR can be used to analyze the gene expression levels of inflammatory molecules such as cytokines. Other more advanced technologies, such as next-generation sequencing and metagenomics, have the potential for rapid identification and classification of pathogenic communities of periodontal viruses, bacteria, fungi, and parasites. Metagenomics can also be applied to classify the periodontal microbial communities and to run longitudinal studies on patients and control groups (Wang et al., 2013a). The understanding that shifts in the composition of the periodontal microbiome can cause disease-related perturbations in the periodontal ecosystem should allow the development of innovative methods for periodontal disease prevention. Thus, the identification of disease-related markers in oral biofluids may lead to the development of tools for the early detection of disease, treatment planning, the prediction of treatment response, therapeutic solutions, and personalized therapies (Jaedicke et al., 2016). This may be augmented by computerized algorithms. In the long term, novel diagnostic and therapeutic methodologies may even permit patients to self-detect and arrest periodontitis (Kornman et al., 2017).

Complexes in periodontitis

Periodontal bacteria in subgingival plaque were originally divided into different complexes, known as the Socransky complexes (Socransky et al., 1998). This classification reflects in part the succession of colonization by microbial species that ultimately form the dental biofilm that causes periodontitis. In fact, early bacterial colonizers are classified in the green complex (including *Eikenella corrodens*, *Campylobacter concisus*, and *A. actinomycetemcomitans* serotype "a"), the yellow complex (including *Streptococcus* species such as *S. mitis*, *S. oralis*, and *S. gordonii*) and the purple complex (including *Veillonella parvula* and *Actinomyces odontolyticus*) (Socransky et al., 1998; Sakamoto et al., 2005; Hajishengallis and Lamont, 2012). These bacteria are able to adhere to the pellicle on the tooth surface and form a basis for other bacteria to colonize the gingival sulcus. The Socransky complexes are also defined by other criteria including their association with the severity of the disease. In particular, the complexes that encompass periodontal pathogens are the orange and red ones. It is important to note that even though defined microbial complexes are a convenient concept that has been commonly adopted worldwide, this view has been challenged by newer studies on the microbiome in periodontitis (Hajishengallis and Lamont, 2012; Caselli et al., 2020). In fact, the increased use of advanced molecular-based technologies for the detection of bacteria, instead of the use of culture-based approaches only, has significantly advanced our understanding of the complexity of the periodontal microbiome in health and disease (Hajishengallis and Lamont, 2012; Bankur et al., 2014; Pérez-Chaparro et al., 2014; Ye et al., 2020). For instance, the distinction between pathogens and commensals is not as clear as previously thought, as it is also dependent on the interactions of bacteria with the host. This would explain the fact that red complex bacteria can be present, although in very low numbers, in healthy individuals (Griffen et al., 1998; Bankur et al., 2014; Carrouel et al., 2016). Moreover, a higher diversity and heterogeneity of the oral microbiome has been recognized recently. Among the newly identified members of the oral microbiome, there are new bacterial taxa that also correlate strongly with periodontitis, including Gram-positive bacteria which, contrary to Gram-negative bacteria, were thought to be less involved in periodontitis (Ye et al., 2020). Newly identified periodontitis-associated bacteria include species of the genera of *Bacteroidetes*, *Prevotella*, *Peptostreptococcaceae*, *Streptococcus*, *Pseudomonas*, and *Selenomonas* (Socransky et al., 1998; Pérez-Chaparro et al., 2014). Thus, it is likely that the species included in each complex might need to be redefined and subjected to possible alterations based on other variables, such as specific polymicrobial interactions and the host-microbiome crosstalk happening in the oral cavity (Yamada et al., 2005; Suzuki et al., 2013). Bacteria of the established periodontal complexes will therefore be grouped and discussed as such, mainly for the sake of convenience, with a clear focus on the more virulent bacteria belonging to the red, orange, and the so-called AA complex.

Red complex

The red complex is considered the climax bacterial community and includes *P. gingivalis*, *Treponema denticola*, and *Tannerella forsythia*, the most important pathogens involved in adult periodontitis (Socransky et al., 1998; Mohanty et al., 2019). These bacteria produce specialized virulence factors that mediate the efficient destruction of periodontal tissues and alveolar bone resorption. *T. denticola* is a small oral spirochete, which is strictly anaerobic and mainly located within the surface layers of the subgingival plaque (Dashper et al., 2011; Mohanty et al., 2019). Important *T. denticola* virulence factors include proteinases, peptidases, cytotoxic factors, flagella, and chemotaxis factors. Notably, its motility and chemotaxis are key for host colonization, its deep penetration into periodontal pockets, and invasion of host cells. Indeed, it has been shown that this bacterium is able to adhere and invade several host cells, including epithelial cells and gingival fibroblasts. Conversely, *T. forsythia* is a Gram-negative anaerobe which requires demanding growth conditions in the lab setting (Malinowski et al., 2019). Recent studies have shown that obese individuals are more likely to develop periodontal diseases due to colonization by this bacterium. Amongst *T. forsythia* virulence factors, cysteine-like proteases are involved in the host tissue damage and dysregulation of the host immune system. Other virulence factors include the protease carilysin and a serpin protein that interferes with several immune mechanisms protecting the bacterium (Malinowski et al., 2019). Interestingly, several studies using periodontitis animal models revealed cooperative interactions between these periodontopathogens, such as coaggregation and modulation of virulence factors (Yamada et al., 2005; Mohanty et al., 2019).

Among the members of the red complex, however, the most studied is probably *Porphyromonas gingivalis*, a Gram negative, non-motile, anaerobic bacterium. Originally a model for the *Cytophaga-Flavobacterium-Bacteroides* (CFB) group, *P. gingivalis*' importance grew concomitantly with the discoveries of its connection to periodontitis and to a plethora of non-oral diseases, such as

rheumatoid arthritis, atherosclerosis, diabetes, and, more recently, Alzheimer's disease. Additionally, *P. gingivalis* has also been associated with oral and pancreatic cancer, respiratory diseases, and nonalcoholic fatty liver disease. Periodontitis' connection with rheumatoid arthritis has been suspected since ancient times, but *P. gingivalis*' role in it, and the underlying molecular mechanisms, had only been recently discovered. *P. gingivalis*' peptidylarginine deiminase (PPAD) or citrullinating enzyme, in fact, appears to drive one of the molecular lynchpins of the association between the two diseases. Citrullination of certain human proteins by this bacterial enzyme is believed to elicit production of anti-citrullinated protein antibodies in the host (Mangat et al., 2010; de Smit et al., 2011; Farquharson et al., 2012; Quirke et al., 2014), potentially leading to rheumatoid arthritis development. Atherosclerosis has also been linked to periodontitis, with this oral disease being a potential risk factor (Humphrey et al., 2008) and its treatment being capable of reducing atherosclerosis biomarkers (Teeuw et al., 2014). This may be due to *P. gingivalis* specifically, as the pathogen was found in 82.61% of clinical samples (Xie et al., 2020), showing several pejorative effects in atherosclerosis pathogenesis (Li et al., 2002; Xie et al., 2020). Conversely, *P. gingivalis*' role in the etiology of diabetes revolves around its role in the induction of insulin resistance in the host. This is achieved through an increase in systemic inflammation, due to several mechanisms, including gut microbiota modulation (Arimatsu et al., 2014), and release of pro-inflammatory mediators (Pradhan et al., 2001; Le Sage et al., 2017; Seyama et al., 2020). Similarly, the connection between *P. gingivalis* and Alzheimer's disease chiefly lies in the pro-inflammatory capabilities of this bacterium. *P. gingivalis*, in fact, seems to be responsible, in mice, for neuroinflammation via cathepsin B expression (Wu et al., 2017), the activation of the TLR4/NF- κ B signaling pathway through its lipopolysaccharide (LPS) (Zhang et al., 2018) and, less directly, by causing the release of host inflammatory molecules such as TNF- α , IL-1, IL-6, and IL-8 (Amano et al., 2004). These inflammatory mediators could also increase blood-brain barrier permeability, further boosting *P. gingivalis*' capacity to cause neuroinflammation (Al-Obaidi and Desa, 2018), and cognitive damage. Additionally, this pathogen seems capable of hindering the host immune response, thereby furthering the inflammation environment that is paramount to Alzheimer's disease pathogenesis. Gingipains, the specialized cysteine proteinases of *P. gingivalis*, also appear to drive neuroinflammation through the proteolytic activation of protease-activated receptor 2 (Liu et al., 2017) and could potentially cause neuronal damage (Dominy et al., 2019).

P. gingivalis has also been associated with several cancer types, albeit with different levels of confidence, possibly due to the different depth of the research in each of these fields. There appears to be an inverse relation between *P. gingivalis* and the survival rate of esophageal cancer patients (Zhang et al., 2019a) and a direct relation between *P. gingivalis* antibody and disease severity (Gao et al., 2018). As a potential mechanism, *P. gingivalis* appears to stimulate tumoral cells and metastasis via the NF- κ B pathway (Meng et al., 2019) or miR-194/GRHL3/PTEN/Akt axis activation (Liang et al., 2020). The association of this periodontal pathogen with pancreatic cancer, instead, has been proposed after studies showed that high levels of serum antibodies against it were linked with a 2-fold increase in disease risk (Michaud et al., 2013) and *P. gingivalis* and *A. actinomycetemcomitans* are related to subsequent increased risk (Fan et al., 2018). Possible underlying mechanisms include expression of TLR pathway-associated genes (Shaik-Dasthagirisahab et al., 2015) and p53 activation (Inaba et al., 2018). Similarly to pancreatic cancer, *P. gingivalis* is associated with a higher risk of oral squamous cell carcinoma, with its presence in tumoral cells reducing patient survival (Wen et al., 2020). Several studies have delved into the potential mechanisms underlying this connection, as described in the "oral cancer" section of this chapter.

Respiratory diseases, such as pneumonia and chronic obstructive pulmonary disease, have also been connected to *P. gingivalis*. In the case of pneumonia, however, this bacterium might contribute to the disease development via interactions with other respiratory pathogens, such as the H1N1 virus (Chen et al., 2018) and *Pseudomonas aeruginosa* (Li et al., 2014b). Similarly, it is believed that the role played by *P. gingivalis* in the etiopathogenesis of chronic obstructive pulmonary disease also involves other pathogens, as their colonization of the airways appears to be facilitated by *P. gingivalis*-associated proteases (Vadiraj et al., 2013).

Lastly, the connection of periodontitis with nonalcoholic fatty liver disease prompted the analysis of an eventual connection between this disease and *P. gingivalis*, showing a higher presence of bacterial DNA in patients, as opposed to controls, (Yoneda et al., 2012) and disease worsening in several *in vivo* studies (Furusho et al., 2013; Nakahara et al., 2018; Sasaki et al., 2018; Nagasaki et al., 2020). Potential mechanisms explaining this connection, aside from the aforementioned ones inducing insulin resistance, include gut microbiome modulation and cytokine cascade induction (Alakhali et al., 2018).

The multifaceted damaging potential of *P. gingivalis* is certainly partly due to its vast array of virulence factors. Among them, the most infamous and best studied are LPS, gingipains, PPAD and fimbriae. LPS is a bacterial endotoxin comprising the conserved region lipid A, core oligosaccharide, and the variable O-specific polysaccharide (Schromm et al., 2000). *P. gingivalis* possesses two forms of LPS, the O-antigen polysaccharide O-LPS, commonly found among Gram-negative bacteria, and the anionic polysaccharide A-LPS. Notably, the latter anchors several virulence factors secreted by the type IX secretion system, such as gingipains and PPAD, to the outer membrane, thus becoming paramount to such proteins' expression of their virulence potential (Gabarrini, Heida, et al., 2018c). The LPS of *P. gingivalis*, however, is also a pro-inflammatory molecule, potentially contributing to neuroinflammation in Alzheimer's disease (Zhang et al., 2018), and to the pathogenesis of atherosclerosis, diabetes (Bhat et al., 2014; Le Sage et al., 2017), and nonalcoholic fatty liver disease (Furusho et al., 2013). Gingipains, on the other hand, are cysteine proteinases located on the outer membrane via A-LPS modification, in outer membrane vesicles (OMVs) and secreted in the outer milieu. They are either arginine-dependent (RgpA and RgpB) or lysine-dependent (Kgp) and are responsible for 85% of the proteolysis occurring outside the cell (De Diego et al., 2014). Gingipains have a potential role in the development of diabetes (Ilievski et al., 2017; Seyama et al., 2020) and Alzheimer's disease (Liu et al., 2017) in mice and rheumatoid arthritis (Wegner et al., 2010; Laugisch et al., 2016). PPAD is one of the most studied proteins of *P. gingivalis* in the context of the association between this bacterium and rheumatoid arthritis, as it is believed to play a major role in the etiology of this disease. This enzyme, which can

convert arginine into citrulline residues in a process termed citrullination, appears to be able to target specific human proteins, thus eliciting the rise, especially in genetically predisposed individuals, of autoantibodies involved in the pathogenesis of rheumatoid arthritis (Gabarrini et al., 2015). Notably, PPAD is the only peptidylarginine deiminase present in a human pathogen, one of the only three present in prokaryotes (Gabarrini, Chlebowicz, et al., 2018a), and it has no phylogenetic relation with mammalian PAD enzymes (Goulas et al., 2015; Gabarrini, Chlebowicz, et al., 2018a). Lastly, fimbriae are employed by *P. gingivalis* in adhesion and invasion processes, biofilm formation, and mobility (Enersen et al., 2013), and appear to be involved in every interaction this pathogen has with its host and other bacteria (Hamada et al., 1998). A class of extracellular polymers, fimbriae are proteinaceous structures stemming from the outer membrane and extending toward the extracellular milieu. *P. gingivalis* possesses two fimbriae: the long fimbriae, composed of FimA subunits, and the short fimbriae, consisting of Mfa1 subunits (Amano, 2010). While structurally different, both fimbriae contribute to periodontitis pathogenesis (Amano et al., 2010).

It is worth noting that most virulence factors of *P. gingivalis* are present in OMVs, nanostructures originated from blebbings of the outer membrane (Gabarrini, Medina, et al., 2018b). The vast majority of their cargo is composed of outer and periplasmic proteins (Ellis and Kuehn, 2010), but they appear enriched in virulence factors, especially gingipains (Veith et al., 2014). The encasing of virulence factors and highly efficient proteases in its OMVs, provides protection to this bacterium from its own highly proteolytic environment. Considering the other functions of *P. gingivalis* OMVs, such as biofilm formation and protein secretion, as they were shown to possess invasive capabilities (O'Brien-Simpson et al., 2009; Xie, 2015; Gui et al., 2016) and were capable of entering host epithelial cells and degrade key receptor proteins via gingipains (Furuta et al., 2009a, b; Zhu et al., 2013), they should be considered an additional and efficient mechanism of delivery of virulence factors, contributing to the already high damaging potential of this oral pathogen.

Orange complex

Orange complex bacteria include many periodontal pathogens such as *Fusobacterium nucleatum*, *Campylobacter rectus*, *Campylobacter gracilis*, *Eubacterium nodatum*, *Prevotella intermedia*, *Prevotella nigrescens*, and *Parvimonas micra*. In the case of *F. nucleatum*, it is known that this bacterium acts as a bridging species linking the early colonizers with late colonizers, which are often highly pathogenic and are classified in the red complex (Diaz et al., 2002; Suzuki et al., 2013). A characteristic that makes *F. nucleatum* a key organism in the formation and maturation of oral biofilms is the adhesin-rich outer membrane, which allows adhesion to other microorganisms and host cells (Thurnheer et al., 2019). Interestingly, the metabolism of the orange complex bacteria creates appropriate living conditions for the red complex bacteria which are strict anaerobes (Diaz et al., 2002; Bourgeois et al., 2019). For instance, *C. rectus* produces protoheme, which enhances the growth of the red complex bacterium *P. gingivalis* (Aruni et al., 2015). Moreover, orange complex bacteria are responsible for the increase in pocket depth and are the most abundant bacteria of the interdental biofilm.

Arguably the most notorious member of the orange complex, *Fusobacterium nucleatum* is a strictly anaerobic Gram-negative bacterium which is one of the most abundant species in the oral cavity (Socransky et al., 1998; Yang et al., 2014). *F. nucleatum* plays an important role in development and progression of oral diseases, such as periodontitis and gingivitis (Saygun et al., 2011), and it is also one of the most prevalent species found in extra-oral infections (Han, 2015). *F. nucleatum*, in fact, plays a role in diseases such as infective endocarditis (Shammas et al., 1993), pneumonia (Nagaoka et al., 2017), neonatal sepsis (Wang et al., 2013b), colorectal cancer (Brennan and Garrett, 2019), and Lemierre's syndrome (Brook, 2013).

F. nucleatum subspecies are very heterogeneous, especially regarding their virulence properties, thus the potential for different diseases varies among subspecies of *F. nucleatum* (Conrads et al., 2002; Henne et al., 2018). Originally, *F. nucleatum* was divided into five subspecies: *vincentii*, *animalis*, *nucleatum*, *polymorphum* and *fusiforme*. According to genetic analyses, the *fusiforme* subspecies was absorbed into the *vincentii* clade (Kim et al., 2010).

F. nucleatum subsp. *animalis* is the most dominant subspecies associated with human colorectal cancers (Ye et al., 2017), while *F. nucleatum* subsp. *polymorphum* is the most prevalent subspecies in the human oral cavity (Henne et al., 2018). *F. nucleatum* was initially found in overabundance in colorectal cancer tissue using metagenomics in two studies (Castellarin et al., 2012; Kostic et al., 2012). Subsequently, more and more reports indicated that *F. nucleatum* played a key role in the acceleration of development and progression of colorectal cancer (CRC) (Flynn et al., 2016; Yamamura et al., 2016; Casasanta et al., 2020).

Although the microbial translocation route of *F. nucleatum* is not clear, it is well accepted that the bacterium may originate from the oral cavity and that it results abundantly in CRC (Brennan and Garrett, 2019; Komiya et al., 2019). One report showed that more than 40% of CRC patients exhibited identical strains of *F. nucleatum* in their CRC and saliva specimens, suggesting the oral-gastrointestinal route as one possible route for translocation (Komiya et al., 2019). Another study showed that an *Apc*^{Min/+} murine infection model, which was fed with *F. nucleatum*, developed enhanced intestinal tumors, thus strengthening this hypothesis (Kostic et al., 2013). However, recently, a study reported that the intravenous route of oral fusobacteria to CRC is more efficient compared to the gastrointestinal route (Abed et al., 2020). A previous study also demonstrated that *F. nucleatum* localized to colorectal tumors via transient physiologic bacteremia (Wilson et al., 2008), while yet another study suggested that *F. nucleatum* can translocate from the mouth to CRC tissues via multiple routes (McCoy et al., 2013).

A better understanding of the mechanisms underlying the role played by *F. nucleatum* in CRC carcinogenesis could develop novel therapeutic strategies for CRC patients. One group demonstrated that *F. nucleatum* can stimulate the proliferation of CRC cells. In the first study, in fact, they showed that FadA, the adhesin and virulence factor of this bacterium, can bind E-cadherin, activate β -catenin signaling, and increase the expression of Wnt genes and inflammatory genes, stimulating the proliferation of CRC cells (Rubinstein et al., 2013). In a later study, the authors showed that ANXA1, either a tumor suppressor or promoter, was activated by *F. nucleatum*, thus selectively stimulating the growth of CRC cells (Rubinstein et al., 2019). Additionally, this bacterium can generate

a proinflammatory microenvironment through recruitment of tumor-infiltrating immune cells, thus promoting tumor cell proliferation (Kostic et al., 2013). Yet, another important mechanism is based on bacterial enrichment. Metagenomic analyses, in fact, demonstrated that *F. nucleatum* localized to and was enriched in human CRC cells and recruited multiple other bacterial species playing a role in the development and progression of CRC (Mitsuhashi et al., 2015). This was possibly due to the binding of *F. nucleatum*'s Fap2 lectin to the Gal-GalNAc expressed by tumor cells (Abed et al., 2016) and to the binding of fusobacterial adhesins, such as RadD (Guo et al., 2017), Aid1 (Kaplan et al., 2014), FomA (Liu et al., 2010), and CmpA (Lima et al., 2017) to other bacterial species such as *P. gingivalis* and *Streptococcus* spp. (Abed et al., 2016). The third mechanism underlying the involvement of *F. nucleatum* in CRC carcinogenesis is based on antitumoral immune evasion. *F. nucleatum*-bound tumors, in fact, are protected from NK-mediated killing and immune cell attack via an interaction between Fap2 and the immune cells' inhibitory receptor TIGIT (Gur et al., 2015). Fap2 was shown to be also involved in *F. nucleatum*-mediated hemagglutination with the hemagglutination potency of Fap2 directly correlated with TIGIT inhibition (Gur et al., 2015). The role of this bacterium in CRC chemoresistance is a prime target for investigation since a deeper understanding of it could easily optimize current treatment. A study reported that autophagy-related pathways are enriched and activated in CRC patients with a high amount of *F. nucleatum*, and that *F. nucleatum* promotes CRC chemoresistance via selectively targeting specific miRNAs and autophagy elements. The ULK1 and ATG7 pathways, in fact, were reported to be activated by *F. nucleatum*, which also caused a selective target loss of miR-18a* and miR-4802, thus this activation of autophagy pathways results in a modulation of CRC chemoresistance *in vitro* and *in vivo* (Yu et al., 2017).

Orange-associated complex and green complex

The bacteria associated with the orange complex are also considered "moderate risk" pathogens of the oral cavity. These bacteria consist of two Firmicutes species and three Proteobacteria, namely *Eubacterium nodatum* (Clostridiales) and *Streptococcus constellatus* (Lactobacillales), and *Campylobacter rectus*, *Campylobacter showae*, and *Campylobacter gracilis* (Campylobacteriales), respectively (Socransky et al., 1998). The green complex, on the other hand, is composed of "early colonizers" of the oral cavity. This complex includes one species of Proteobacteria named *Eikenella corrodens* (Neisseriales) and three Bacteroidetes from the genus *Capnocytophaga* (Flavobacteriales), which include *Capnocytophaga gingivalis*, *Capnocytophaga ochracea*, and *Capnocytophaga sputigena* (Socransky et al., 1998).

AA-complex

The AA-complex comprises the bacterium *Aggregatibacter actinomycetemcomitans*. *A. actinomycetemcomitans* is a Gram-negative, facultative anaerobic, capnophilic bacterium with non-motile and non-sporulating qualities (Henderson et al., 2010; Gholizadeh et al., 2017). *A. actinomycetemcomitans* is associated with both oral and non-oral infections. Localized aggressive periodontitis (LAP) in adults and juveniles is an oral infection associated with this bacterium (Slots et al., 1980), which results in loss of connective tissue and of alveolar bone (Krueger and Brown, 2020). Therefore, the presence of *A. actinomycetemcomitans* can act as an indicator for the initiation of LAP (Slots et al., 1980; Fine et al., 2007). Soft tissue abscesses, osteomyelitis, and endocarditis are the non-oral infections linked with *A. actinomycetemcomitans*, of which the latter one is the most common (Van Winkelhoff and Slots, 1999).

The known isolates of this bacterium can be divided into seven serotypes (a–g). The differences between these serotypes relate to the structural differences in lipopolysaccharide O-antigens, also called specific polysaccharide antigens (SPAs) (Perry et al., 1996; Fujise et al., 2008; Johansson et al., 2017). Other structural differences are evident in the division between rough and smooth phenotype. Fresh isolates of the bacterium display the rough phenotype, which results in transparent colonies and is characterized by fimbriae on the surface and a star-shaped colony structure. In the smooth phenotype, the fimbriae and star-shaped colony structure have disappeared, and the colonies are opaque. This conversion from rough to smooth occurs spontaneously after long-term passages (Wang et al., 2005; Pei et al., 2013).

Zambon et al. showed that strains of *A. actinomycetemcomitans* isolated from patients with periodontal disease produced significant amounts of the leukotoxin LtxA, while isolated strains from healthy patients produced sensibly less LtxA (Zambon et al., 1983). LtxA is a 113 kDa protein and one of the main virulence factors of *A. actinomycetemcomitans*. The *ltx* operon contains four genes (*ltxC*, *ltxA*, *ltxB*, and *ltxD*), with an upstream promoter (Johansson, 2011). The secretion of LtxA is facilitated by the type I secretion system but, to transport LtxA to the outer membrane, a periplasmic channel (LtxD) and an outer membrane pore (LtxC) are required. LtxB is an ATPase that transports LtxA throughout the whole process (Johansson, 2011). An increased concentration of LtxA was shown to decrease the proliferation of human microvascular endothelial cells in a tetrazolium-based assay (Dietmann et al., 2013). LtxA was further shown to induce apoptosis in human microvascular endothelial cells and increased expression of ICAM-1 and VCAM-1, leading to pro-inflammatory effects in human brain endothelial cells (Dietmann et al., 2013).

Another important virulence factor of this bacterium is the genotoxic cytolethal distending toxin (CDT) (Gholizadeh et al., 2017), encoded by the *cdtABC* operon. CDT is capable of disrupting the cell cycle in fibroblasts during the G1 and G2/M phase through the p53-dependent pathways. Gingival fibroblasts incubated with the wild-type strain of *A. actinomycetemcomitans* showed an increased proportion of cells in the G2/M phase, while a *cdt* mutant showed the same distribution of cells in the G1 and G2/M phases as the untreated control group (Mayer et al., 1999; Belibasakis et al., 2004). CdtB is the functional subunit of CDT, which is able to induce cell cycle arrest due to its type I deoxyribonucleases activity that leads to DNA double-strand breaks (Lara-Tejero and Galan, 2000). Confocal microscopy showed that CdtB on its own does not bind or enter HeLa cells, but CdtA and CdtC do bind the cell wall. CdtB and CdtC together were shown to localize in the cytoplasm of HeLa cells, so CdtC appears to enter the cell along with CdtB (Akifusa et al., 2005). Jurkat cells were exposed to different *cdt* mutants (*cdtA*, *cdtB*, *cdtC*, *cdtAB*, *cdtBC*, and *cdtABC*), and all

these mutant *A. actinomycetemcomitans* bacteria were shown to result in a lower percentage of cells in the G2 phase compared to the wild-type strain. Thus, a mutation in one or more of the three *cdt* genes results in a decrease in toxin activity (Shenker et al., 2004).

Another important virulence factor of *A. actinomycetemcomitans* is its LPS, which stimulates bone resorption (Raja et al., 2014; Belibasakis et al., 2019). LPS has, in fact, multiple virulence-related properties. For example, LPS causes the widening of the spaces between the cells in primary tissue cultures (Belibasakis et al., 2019). Fibroblasts of gingival tissues naturally ingest, and digest collagen, but this process was enhanced by LPS. This can result in an imbalance in the regeneration of gingival tissue. LPS also enhanced the production of cytokines including IL-8, IL-6, and IL-15, which results in a cascade of immune responses (Belibasakis et al., 2019). The patterns of LPS are different in rough and smooth strains of *A. actinomycetemcomitans*. As measured with the classical Limulus lysate assay, the endotoxin activity was higher in the rough isolates than in the smooth strains, suggesting that the rough phenotype has a higher potential for LPS-related pathogenicity (Fine et al., 1999).

There are several additional virulence factors in *A. actinomycetemcomitans*, including the morphogenesis protein C (MorC), which has an influence on the fimbrial selection and microcolony formation that is essential for membrane morphology and leukotoxin secretion (Smith et al., 2016). The tight adherence (Tad) protein is required for production of fimbriae and, accordingly, this protein is important for colonization and virulence of *A. actinomycetemcomitans* (Kachlany et al., 2000; Oscarsson et al., 2019). Further research, however, needs to be done on the virulence factors of *A. actinomycetemcomitans* and their concerted actions, as this will be key to develop novel treatment strategies for all the diseases in which this pathogen is implicated.

Noma

Noma, or cancrum oris, is an opportunistic gingival infection mainly affecting poor and undernourished children aged 2–16 years in low-income countries (Falkler et al., 1999a, b; Enwonwu et al., 2000). Some communities in Sub-Saharan Africa reach an estimated frequency of 1 to 7 cases in every 1000 children, even though actual numbers are thought to be significantly higher, since most cases remain unreported. Without treatment, the mortality rate lies between 70% and 90% (Barnes et al., 1997). Noma causes orofacial necrotizing lesions and severe deterioration of multiple soft and hard tissues, leaving survivors with surgery-requiring disfigurements that may reach up to the cheeks, upper and lower lips, and the nose (Coupe et al., 2013). The infection causes irreversible deterioration of the maxilla, muscles, and mucosal tissues (Lazarus and Hudson, 1997). Key risk factors for Noma include malnutrition, especially vitamin A deficiency, poverty, poor (oral) hygiene and infectious diseases (Enwonwu et al., 2000). These factors, in fact, result in impaired host resistance, which again promotes secondary infections and the etiopathogenesis of this disease. This, in a way, makes poverty the main causative agent for the appearance of the disease.

Noma was for a long time thought to start as a necrotizing ulcerative gingivitis, which is an inflammation of the interdental papillae. However, this theory has been challenged and the cause for the development of Noma remains unclear. Accordingly, no specific infectious agents have been identified to cause the development of Noma from necrotizing ulcerative gingivitis (Enwonwu et al., 2006). Even with the high prevalence of ulcerative gingivitis presented in undernourished Sub-Saharan African children, in fact, only few of them develop Noma (Enwonwu et al., 2006). The disease onset of Noma usually implies the presence of an accompanying bacterial, viral, or parasitic infection (Barnes et al., 1997). Microbiologically, the infection appears polymicrobial in nature, involving bacteria such as the spirochete *Treponema vincentii*, in association with an anaerobe, usually a *Fusobacterium*, and *Prevotella intermedia* (Falkler et al., 1999a, 1999b; Feller et al., 2019). Additionally, HIV, herpesviruses, and measles have been frequently observed as co-infections or reported shortly prior to the diagnosis with Noma in the medical history of affected individuals (Feller et al., 2019). Descriptions of the initial stages of the infection remain inconsistent since patients usually seek medical help once the infection is already well-established. Early symptoms include foul-smelling halitosis, purulent oral discharge, dark coloration of the affected region, and a rotten taste (Baratti-Mayer et al., 2003). When left untreated, Noma usually progresses to the labiogingival fold and subsequently invades the mucosal tissues of the lips and cheek (Coupe et al., 2013). As soon as the infection has reached the soft tissues surrounding the gingiva, further progression causing cheek perforation happens within days and therapy is mostly ineffective (Enwonwu et al., 2006). In those cases, death is typically caused by starvation, as well as sepsis or pneumonia which are common complications of the infection (Baratti-Mayer et al., 2003). Severe disease evolution can be prevented in case of early detection in the gingival stage. The treatment of Noma includes broad spectrum antibiotics, disinfection of the affected area, nutritional recovery, and treatment of the predisposing infection (Feller et al., 2014).

Noma prevention in form of educational campaigns, improvement of hygiene, proper nutrition, vaccination and/or treatment of possible accompanying and co-infections such as measles are main strategies to control Noma outbreaks. However, healthcare workers and individuals in affected communities are still largely under-informed about Noma, which makes educational work a priority to avoid fatal disease development (Enwonwu et al., 2006). Simultaneously, further research to find the cause for Noma development and an effective therapeutic approach for late-stage Noma infections remain urgently needed.

Conclusion

In conclusion, the plethora of bacteria living in the oral cavity and forming the oral microbiome plays an important role in the preservation of our oral and general health. Dysbiotic changes in the oral microbiome, or even specific microbial profiles, can result in a multitude of highly damaging oral diseases, but they may also lead to complications or disorders in other body sites. Specific oral pathogens, especially, are capable of bringing about several far-reaching consequences. For example, *Porphyromonas gingivalis* is

either a causative agent, risk factor, or believed to play a role in the etiopathogenesis of several diseases, oral or systemic, such as periodontitis, cardiac and respiratory diseases, diabetes, Alzheimer's disease, nonalcoholic fatty liver disease, oral and pancreatic cancer, and rheumatoid arthritis. Similarly, *Fusobacterium nucleatum* has been connected to several different cancer types, such as oral, colorectal, and pancreatic cancers. However, with new analytical technologies and the ever-increasing number of new studies focused on oral diseases, oral pathogens, and the molecular mechanisms connecting the two, it will be easier to unlock the full damaging potential of the oral microbiome, thus relieving the global economic burden of oral diseases and improving, or saving, the life of millions of patients worldwide.

Introduction

The oral cavity includes a number of different habitats, such as teeth, tongue, cheeks and gingiva, which are colonized by bacteria. The Human Oral Microbiome Database currently includes some 775 microbial species (Escapa et al., 2018). Viruses are difficult to detect with traditional methods such as in vitro cultivation; however, the advent of the tools of molecular biology, particularly various PCR-based methods, has changed the situation. We can now readily detect not only bacteria that do not grow in culture, but also viruses. Viruses are surprisingly common in the oral cavity; consequently, it is important to know what role they play, if any, in oral disease. The topic has been reviewed elsewhere (Clarkson et al., 2017; Grinde and Olsen, 2010), below follows an updated overview.

It is well known that most of the bacteria associated with your body do not cause any harm. Viruses have a more dubious reputation. The main reason why they in the eyes of clinicians are more closely associated with diseases is presumably the fact that they have been less visible. While it is easy to find numerous species of bacteria in samples from a healthy mouth, even after the advent of PCR, people rarely look for viruses except as suspects when diagnosing a particular clinical condition. If a virus is detected, it is typically assumed to contribute to that condition. We now know that some viruses are highly prevalent in the human body. Viruses of the family *Anelloviridae* are present in more than 90% of adults (Moen et al., 2002; Huang et al., 2001); they have been suggested to play a role in a number of diseases, but so far no obvious role in pathogenicity has been elucidated. The same can be said about the closely related *Circoviridae* (Sauvage et al., 2018; Rosario et al., 2017). Polyomaviruses are present, at least in some points in life, in a majority of the population, but are only rarely associated with any symptoms (Jiang et al., 2009). Moreover, even viruses that are known to be capable of serious complications can be highly prevalent in people without any overt symptoms; examples include the herpesvirus family and enteroviruses. Many of these viruses presumably rely on an oral or fecal-oral route of transmission, thus a presence in the oral cavity would not be unexpected.

The ubiquity of the above-mentioned viruses implies that their detection in samples taken from diseased oral tissue is not sufficient to implicate the virus in pathological changes. The focus of this review is on viruses that may be directly responsible for clinical symptoms – as opposed to those that simply use an oral route of transmission without manifesting themselves in the mouth. Some viruses affect oral health indirectly. HIV is one example as the immunodeficiency caused by the virus, typically manifest itself by oral infection of other agents such as *Candida*.

Clinical aspects

The process of evolution has shaped viruses according to the same principles as other organisms, that is, they are tuned to survival and procreation. As with any obligate parasite, a winning strategy requires not just efficient replication, but also a means of transmission between hosts. Consequently, it is not an optimal strategy to kill the host; in fact, it is generally preferable to reside in a physically active, implying healthy, host. Unfortunately, evolution rarely forms optimal organisms.

One feature that distinguishes viruses is their extreme form of what in biology is referred to as ‘r-selection.’ The term is used for organisms that produce as much progeny as possible without bothering about quality assurance or putting resources into each one of them. This strategy allows the virus to have a more sloppy machinery for RNA or DNA replication than any cellular organisms; viruses can afford to make thousands of worthless copies of themselves for each competent viral particle. The point is a nightmare for clinicians, in that viruses relatively easily develop resistance to antiviral medication, in that they escape vaccines or the immunological memory of previous infections, and in that their variability makes the DNA/RNA based diagnostic tools less certain.

Although viruses as a rule of thumb are best served by having a healthy host, they still cause serious disease. Three factors are of particular importance for the clinical outcome of a viral infection:

Table 1 Common clinical symptoms caused by viruses – according to transmission strategy.

<i>Strategy</i>	<i>Symptom/disease</i>	<i>Relevant viruses</i>
'Hit-and-run' viruses	Coughing Diarrhea Bleeding	Influenza, rhino- and coronaviruses Noro- and rotaviruses Ebola- and hantaviruses
Chronic viruses	Blisters, soars, ulcers Behavioral change, e.g. aggression	Herpes- and enteroviruses Rabies virus
Clinical symptoms with no obvious viral strategic cause	Cancer Immunodeficiency Fever Gross immunological overreaction and secondary infections	Papilloma- and polyomaviruses HIV and coronaviruses Many viruses Pathogenic influenza and SARS coronaviruses

- 1) Pathology depends on how advanced the relationship between virus and host is. Viruses that have a long evolutionary history with a particular species generally evolve mechanisms to avoid unnecessary damage to their host; while viruses that recently jumped from one species to another, have not had the chance to do so. Consequently, zoonotic viruses pose a particular threat to human health.
- 2) Symptoms also depends on whether the virus is designed to remain within the host for a long time, preferably throughout the life span; or if it is a 'hit-and-run' virus. In the latter case, there is obviously less selection as to restraining the virus from causing harm.
- 3) The final factor is whether the virus requires particular behavior or symptoms of the host in order to be transmitted to another individual. Coughing, vomiting and diarrhea are perhaps the most obvious and well-known examples. In [Table 1](#), the various strategies and clinical symptoms are outlined schematically.

Viruses can infect any type of cell in the human body, with the exception of erythrocytes; still the oral cavity has a particular significance. For one, the mouth offers a perfect entrance to a new host. We breathe, drink and eat every day; thus all that is required for the virus is a strategy that allows transmission either through air or through water/food. The former is typically cared for by the infected host when he coughs and thus sends out aerosols containing viral particles (but simple breathing can be sufficient); the latter is reflected in transmission by the fecal-oral route; that is, the virus infects the guts and is thus released to the environment through the feces. The central location of the mouth reflects that several viruses can be diagnosed by the use of oral/throat samples (e.g., swabs) even though they are unlikely to contribute to oral pathogenicity ([Corstjens et al., 2016](#)). Some viruses will occasionally manifest themselves in the oral cavity, although they primarily cause disease elsewhere. The measles virus, for example, can trigger small, white spots in the mouth, while its typical manifestations are skin rash and systemic symptoms.

Respiratory viruses

Respiratory infections, including the common cold, are mostly due to viruses. The more common culprits belong to rhinoviruses, coronavirus, adenoviruses, and influenza. These viruses primarily replicate in the upper respiratory tract; more rarely, they are active in the oral cavity or find their way down to the lungs. Their typical strategy of aerosol transmission does not require replication in the mouth, in fact in order to induce a cough, it is more appropriate to cause irritation of the throat.

This statement is true for SARS-CoV-2, the virus responsible for covid-19, as well. Although the main receptor for this virus (ACE2) is expressed in oral mucosa, particularly on the tongue (as well as in a variety of other tissues), the virus is apparently not very active in the oral cavity ([Xu et al., 2020](#)). There are, however, some case reports that associate SARS-CoV-2 with vesiculobullous lesions (painful ulcers or blisters) in the oral mucosa, as well as pain in the tongue ([Carreras-Presas et al., 2020](#)). Although the causative nature of the association is not definite, it would neither be unexpected.

Herpesviruses

In the case of some viruses, replication in the mouth may be preferable. Humans are not the only species that have developed a delight in kissing, but probably no other species are prone to engage in the exchange of sputum to the extent that we humans are. Some viruses have apparently adapted to this behavior in their approach to the question of transmission. In order to assure continuous viral presence in sputum, it is preferable to replicate in cells lining the oral cavity and to release viral particles to the saliva. Herpesviruses (and possibly papillomaviruses) are among the viruses that presumably use this strategy. Replication in oral tissue places the oral cavity more at risk for clinical symptoms.

Table 2 Human herpesviruses (HHV) and their associated diseases.

Type	Primary target cell	Oral affection	Other pathology
Herpes simplex virus-1	Mucoepithelial	Herpes ulcers ("cold sores")	Genital ulcers
Herpes simplex virus-2	Mucoepithelial	Herpes ulcers ("cold sores")	Genital ulcers
Varicella Zoster virus	Mucoepithelial	Possible oral manifestations of chicken pox and herpes zoster	Chicken pox, herpes zoster (shingles)
Epstein-Barr virus	B-cells and epithelial cells	Hairy leucoplakia, oral lymphomas, periodontitis?	Mononucleosis, lymphoma
Cytomegalovirus	Monocytes, lymphocytes and epithelial cells	Oral ulceration, periodontitis?	Mononucleosis
Human herpesvirus-6	T-cells and possibly others	No known oral manifestation	Roseola in infants
Human herpesvirus-7	T-cells and possibly others	No known oral manifestation	Roseola in infants
Human herpesvirus-8	Probably lymphocytes and epithelial cells	No known oral manifestation	Kaposi's sarcoma (in AIDS patients)

Herpesviruses have a double-stranded DNA genome and are among the largest and most complex human viruses. There are eight members of the human herpesvirus (HHV) family (Table 2). The more common, as to oral health problems, are the two herpes simplex viruses (HSV-1 and -2), which cause recurrent herpetiform ulcerations referred to as cold sores. These ulcers typically occur on the lips, but the viruses can also cause similar lesions in the mucosa, such as in the case of gingivostomatitis. The mucosal affection is normally associated with a primary herpes infection in children, and is accompanied by bodily symptoms such as fever and malaise. Both HSV-1 and -2 are involved in the above oral manifestations, although the latter is traditionally associated with the genitals.

Epstein-Barr virus (EBV) and cytomegaloviruses (CMV) are present in the vast majority of adults, but in most cases presumably without causing any overt disease. Both can, however, cause mononucleosis; EBV being responsible for most of the cases. Mononucleosis is also known as 'kissing disease,' suggesting that the virus spreads by direct mouth-to-mouth contact. The condition is associated with teenagers; the name reflects that this is the time when people start kissing. The cause of the disease, however, is most likely a lack of contact with these viruses early in life. EBV and CMV are adapted to be reasonably ubiquitous and not to cause overt symptoms in youngsters. The sanitary conditions of modern societies are likely the main culprit as to the prevalence of mononucleosis.

EBV's potential for affecting the mouth is further underlined by oral hairy leucoplakia. The disease is characterized by white patches, typically on the side of the tongue, with a hairy appearance. The condition is restricted to immunosuppressed patients.

Varicella-Zoster virus (VZV) is associated with chicken pox, when active in a primary infection, and with herpes zoster if reactivated later in life. The vesicular rash formed occurs primarily in the skin, but may also affect the mucosa. The three remaining human herpesviruses (HHV-6, -7 and -8) rarely cause serious disease, but the former two are responsible for a particular type of skin rash (roseola) with associated fever in infants.

The herpesviruses typically form chronic infections. The virus remains with its host until death do them apart; much of the time in latency, but with occasional bursts of activity. As these viruses are contact transmitted, either by means of virus production in the skin accompanied by rashes and blister or viral presence in sputum, it is not surprising to find viral activity in the oral cavity. In addition to the traditional clinical picture referred to above, EBV and CMV have been associated with periodontitis (Grinde and Olsen, 2009). Several laboratories have demonstrated that these viruses are found significantly more frequently in samples taken from affected 'pockets' around the teeth compared to healthy pockets (Slots, 2004; Sunde et al., 2008a), however, this association does not necessarily mean that they are involved in the pathology. The number of viral genomes observed is generally low, which has led some to doubt any clinical significance (Aggarwal et al., 2017). One person with recurrent periodontal disease, who had a particularly high EBV-load subgingivally, was successfully treated with antiviral treatment (Sunde et al., 2008b), suggesting that EBV does play a role at least in some patients.

In general, it makes sense to be skeptical as to pathogenicity when the viral load is limited. Both EBV and CMV are found occasionally in any mouth, as long as a relevant sample of sufficient size is analyzed by a sensitive technique. EBV, in particular, tends to be cyclically active in the body and thus periodically present in sputum. Associations between viruses and the severity of the condition, or between viruses and the presence of particular bacterial species, may be explained by confounding factors; for example, a more active inflammation would be expected to correspond to the presence of certain bacteria, and cause more pain, but also to contain more lymphoid cells and/or more body fluids. These two factors could explain a viral association, as both EBV and CMV replicate in leukocytes and are shredded to the extracellular fluid.

Antiviral treatment seems to be the best way to indicate the actual role of EBV or CMV in periodontitis. Moreover, if successful, it may save the patients from considerable pain and agony. Quantitative antiviral tests, such as real-time PCR, are relevant in the management of these patients, maybe particularly in chronic and aggressive cases for which other therapy fails. If the tests find appreciable amounts of virus, antiviral treatment should be considered as an adjunct to conventional periodontal therapy. It should be noted that the latter form of therapy has also been reported to reduce the viral load (Grenier et al., 2009).

Enteroviruses

The enteroviruses belong to the family *Picornaviridae*. Enteroviruses have a single-stranded RNA genome and are classified into five species with all together more than a hundred subtypes. Although the majority of human enterovirus infections are asymptomatic (Witso et al., 2006), they can cause upper respiratory illness, febrile rash, aseptic meningitis, pleurodynia, encephalitis, acute flaccid paralysis and neonatal sepsis-like disease (Romero and Modlin, 2015).

As to oral affection, the enteroviruses are primarily associated with hand, foot and mouth disease. This is a febrile illness with tender papulovesicular lesions of both the hand, feet and oral mucosa (Wong et al., 2010). It occurs mostly in children, but can also affect adults. The association with enteroviruses primarily concerns the type A viruses (including Coxsackie virus A16 and enterovirus-71), but other enteroviruses may also be involved. Herpangina is a related condition where the clinical manifestation is primarily in the oral cavity in the form of ulceration and blisters. Again, the condition is rare and restricted to children.

Papillomaviruses

Human papillomavirus (HPV) is a DNA virus that can chronically infect either skin or mucosal epithelium. Parts of the viral genome are occasionally integrated in the DNA of the host cells, and some of the genes are assumed to have a malignant potential, as reviewed elsewhere (Berman and Schiller, 2017). The role of HPV in cervical cancer is well accepted and has led to the widespread use of papillomavirus vaccines for young women. Related carcinomas occur in the mouth cavity, as well as in the oropharyngeal area.

HPVs are considered responsible for various forms of papillary lesions in the oral cavity, including squamous papillomas, condylomas, and multifocal epithelial hyperplasia (Betz, 2019). Although these viruses appear to be involved in many cases of malign oropharyngeal cancers, there is a distinct cohort of cancer patients that are HPV negative (Evans et al., 2013). In this cohort, the disease is typically associated with other risk factors such as tobacco and alcohol. The observed prevalence of oral cancers is considerably lower than what is reported for cervical cancers; still the case favoring a role of these viruses is reasonably strong. Based on the viral role in cervical carcinomas, the viruses are classified as having either high (primarily subtype 16 and 18) or low (including subtype 6 and 11) oncogenic potential.

In a recent systematic review, it was concluded that approximately 7.7% of healthy subjects harbor HPV in the oral region (Tam et al., 2018). The prevalence is typically reported to be higher in biopsies from oral lesions such as leucoplakia or cancers. In the former case, the association with oncogenic HPVs is less obvious; while in the case of malignant cancers, most laboratories find a definite overrepresentation of the more malignant HPVs (Giuliano et al., 2008).

HPV vaccines have been generally available since 2006, and appear to have caused a major reduction of cervical cancer (de Sanjose et al., 2019). There is also a reduction in penile cancers and warts, presumably due to the indirect effect of men being less exposed to these viruses when having unprotected sex due to their drastically reduced prevalence in women. There is a general reduction in oral HPV infections, but the expected reduction of oral cancers is not yet verified.

The main argument against vaccinating both sexes is the calculated cost/benefit ratio. Relevant forms of cancer have a considerably lower prevalence in males compared to females. Moreover, as the virus forms chronic infections, vaccination of individuals who already contain the potentially malign subtypes is considered less useful.

Interactions between viruses and other microbes

Herpesviruses are well known for their capacity to manipulate the immune system; for example by producing cytokine mimics designed to modulate the host's immune defense. Although the obvious purpose of manipulation is to boost viral replication, it is easy to envision that a down-regulation of immunological surveillance may also benefit other agents present, such as bacteria. There are data suggesting that viral activity in periodontal tissues may impact on the local immune response in a way that benefits opportunistic bacteria and thus leads to aggravated symptoms (Chen et al., 2020). For example, the bacterial profiles in samples obtained from periodontic sites depend on the presence of virus. It should be noted that the microbial activity can stimulate viral replication, as has been shown in the case of EBV and malaria (Chène et al., 2007).

Bacteriophages

It has been estimated that the mouth is typically home to some six billion bacteria, and possibly 35 times as many viruses (Edlund et al., 2015). The majority of the latter are presumably not human viruses, but bacteriophages – viruses that replicate in bacteria. The reason for this imbalance is that bacteria vastly outnumber human cells associated with the oral cavity. The fact that the bacteriophages only indirectly have a human host, does not make them irrelevant as to oral health. They do modulate the microbial ecosystems they inhabit; for example by transferring genes such as those responsible for antibiotic resistance. As such, they can either act to the benefit of a patient suffering from oral bacterial infections, or increase the severity of the symptoms. The point is relevant in connection with periodontitis (Edlund et al., 2015).

Diagnostics

Viral diagnostics have become more relevant in clinical dentistry. This is partly because of an increased awareness that viruses are possible etiological agents, and partly because the methods of viral detection have become considerably cheaper and easier. The preferred methods are based on variants of real-time PCR, which not only offer a test for the presence of virus, but also yield quantitative data. The latter point is particularly relevant as several viruses can be present in healthy oral mucosa. However, a high viral load in a sample taken from affected tissues does suggest a pathogenic association with the underlying condition.

A major limitation as to this association is that some of the viruses that are chronically present in the body replicate in leukocytes (e.g. EBV and CMV). Clinical samples are typically taken from inflamed tissues, such as periodontal pockets or ulcerations; consequently, one might expect a presence of these viruses due to the accumulation of leukocytes. The point has been demonstrated in the case of CMV and periodontitis (Sabeti et al., 2009). Again, a clinical role is suspected if the titer is particularly high, and even more so if the condition improves upon antiviral treatment.

A main limitation of PCR-based methods is that they only detect the viruses (or nucleic acid sequences) they are designed to detect. Several novel human viruses have appeared during the last decade, and most likely the human body is the host to a range of viruses that are yet to be described. Moreover, the cost of the methods restricts analyses to relatively few viral types; thus the total spectrum of potentially relevant viruses is rarely tested. Two strategies compensate for this limitation: microarrays and pyrosequencing. In microarrays, probes detecting different viruses (or other agents) can be applied to a slide and the sample DNA or RNA hybridized onto the slide, thus offering a possible detection of all known viruses. In pyrosequencing, the complete nucleic acids present in the sample are sequenced to look for recognizable viral sequences by searching relevant databases. Both these methods have the same two limitations; they are less sensitive than PCR, and they are considerably more expensive. Consequently, the techniques are not suitable for routine diagnostics, but are relevant in scientific inquiries seeking to outline viral involvement in various conditions. One such case is the common aphthous ulcers, also known as canker sores. Although viruses have been implicated by their presence in clinical samples (Lin et al., 2005), it seems unlikely that the true viral culprit, if any, has yet been found.

Introduction

Fungi are a large and complex group of eukaryotes organisms. Among these, *Candida* species should be highlighted, which produces most of the fungal infections that affect the oral cavity. *Candida* is a ubiquitous polymorphic fungus that is commonly found in the gastrointestinal tract and other mucous membranes, as well as, on the skin. The genus *Candida* comprises more than 200 species and most of them are dimorphic yeasts (Bhattacharya et al., 2020; Bandara and Samaranayake, 2019; Lewis and Williams, 2017; Telles et al., 2017; Hellstein and Marek, 2019). Of the different *Candida* species (Table 1), *C. albicans* is the most prevalent in the oral cavity and is isolated in 90–95% of cases. Apart from *C. albicans*, there are other isolated species with much less frequency such as *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, *C. pseudotropicalis*, *C. dubliniensis*, *C. lusitaniae*, *C. krusei*, *C. guilliermondii*, *C. stellatoidea*, *C. inconspicua*, *C. norvegensis*, *C. rugosa*, and *C. auris* (Lombardi and Ouanounou, 2020; Bhattacharya et al., 2020; Hellstein and Marek, 2019; Hoare et al., 2017; Lewis and Williams, 2017; Telles et al., 2017). In some cases, several *Candida* species can be associated, being *C. albicans* and *C. glabrata* the most frequent association, followed by *C. albicans* and *C. tropicalis* (Swidergall and Filler, 2017).

Besides the species of the genus *Candida*, there are other types that lead to fungal oral infections less frequently, especially in immunosuppressed patients. They are *Geotrichum*, *Aspergillus*, *Histoplasma*, *Cryptococcus*, *Blastomyces*, *Coccidioides*, *Saccharomyces*, *Penicillium* and *Geotrichum*, among others (Bandara and Samaranayake, 2019; Lewis and Williams, 2017).

Fungal infections of the oral cavity are common, especially oral candidiasis (OC). In most cases, they are superficial infections but in some cases are invasive and can progress to disseminated infections, increasing morbidity and mortality (Bhattacharya et al., 2020; Telles et al., 2017). The prevalence of OC varies according to age and the population studied. It should be noted that *Candida* carriage is present in the oral cavity of 20–85% of healthy patients. Therefore, the presence of *Candida* is not a good predictor of the disease (Bandara and Samaranayake, 2019; Bugshan et al., 2017; Hellstein and Marek, 2019; Lewis and Williams, 2017). In fact, according to certain studies that do not use cultures to identify the oral fungal microbiome but molecular detection methods, *Candida* species are present in all the patients studied (Peters et al., 2017).

Pathogenesis

C. albicans is a commensal fungus that is commonly found in the oral cavity in balance with the rest of the oral microbiome and host's immune system. In certain cases, when this balance is altered *Candida* yeast can change from commensal to pathogen, causing superficial infections and in some cases, especially in immunosuppressed patients, it can produce systemic infections (Hube and Naglik, 2001). The change from commensal to pathogen is complex and it is usually due to changes in the local environment and

<i>Geotrichum</i>	<i>Geotrichum candidum</i>

systemic state of the host. This results in an increase in the growth of *C. albicans* strains and in the expression of its virulence factors (Quindos et al., 2019). Likewise, the oral microbiome also has an influence, when the number of bacteria decreases the number of *Candida* species increases (Lewis and Williams, 2017). The most relevant points of OC pathogenesis will now be reviewed.

Ability to form biofilms

C. albicans has the ability to form biofilms on different surfaces such as oral mucosa, teeth, dentures and orthodontic appliances (Quindos et al., 2019). The formation of biofilms is a dynamic process, which begins with the adherence of *C. albicans* strains which must proliferate, form hyphae, and accumulate extracellular matrix, as will be seen below.

Two types of *C. albicans* cells are involved in biofilm formation: the blastospores or small yeast-form cells, and the long tubular hyphal cells (Wibawa, 2016). The biofilm matrix of *C. albicans* is composed of polysaccharides β -1,3-glucan, β -1,6-glucan, and mannans that form the mannan-glucan complex (MGCx) (Vila et al., 2020). When the biofilm is established, the expression of *Candida* virulence factors increases, and the susceptibility to host phagocytosis and antimicrobials decreases. Evidence shows that the formation of *C. albicans* biofilm is associated with resistance to antifungal therapy. Biofilm protects and promotes metabolism cooperation, and improves resistance to physical and chemical stress (Wibawa, 2016). In addition, the presence of bacterial components in the oral microbiome also play an important role in the appearance and exacerbation of lesions (Vila et al., 2020).

Adherence to oral mucosa and other surfaces

Adherence to oral mucosal epithelial cells, dentures, and orthodontic appliances is the first step in the development of *C. albicans* infection. By adhering, it prevents be damaged by salivary antimicrobial agents, be removed by saliva and allows to repopulate the epithelial tissue when it is replaced (Lewis and Williams, 2017). *C. albicans* adhesion is carried out through electrostatic interactions with the epithelial surface by cell-wall receptors. Besides, there are some virulence factors called adhesins that collaborate binding *C. albicans* to epithelial cells and polymers of dentures (Wibawa, 2016). Some of the most studied *C. albicans* adhesins are the agglutinin-like sequence (ALS) glycoproteins such as Als3p and hyphal wall protein Hwp1 (Vila et al., 2020).

Invasion and cell damage

C. albicans invades the oral epithelium by two different mechanisms. The first is endocytosis. To do so, it changes its morphology and phenotype which facilitates penetration into the epithelium (Quindos et al., 2019). *C. albicans* has the ability to grow both in the form of yeast and mold. This ability to change from a yeast form to a hypha form is called dimorphism. Dimorphism is a fundamental characteristic of *C. albicans* that favors its virulence. Passage from yeast to filamentous form collaborates in the different stages of the infection (Wibawa, 2016). Besides, *C. albicans* has another feature called phenotypic switching. It has been observed how certain *C. albicans* isolates, which are homozygous at the mating type locus (*MTL*, *a/a* or α/α), can change between two different cell morphologies: white and opaque. These cell morphologies are different in their mating ability and expression of genes related to adhesion and metabolism (Wibawa, 2016).

The changes of phenotype and morphology are due to different environmental stimuli. A relevant property of hyphal cells is thigmotropism or their ability to grow after contact with a surface, which favors endocytosis and invasion of intercellular junctions (Vila et al., 2020). The hyphae of *C. albicans* express the adhesins Als3p and invasin Ssa1 (member of the HSP70 family of heat shock proteins), which bind to E-cadherin and a heterodimer composed of the epidermal growth factor receptor (EGFR) and HER2 on the surface of the epithelium (Sun et al., 2010; Swidergall and Filler, 2017). These processes cause clathrin-dependent endocytosis machinery that induces epithelial cells to produce pseudopods that engulf the fungus and drag it into the interior. There are signaling pathways that are necessary for endocytosis to occur, including platelet-derived growth factor BB (PDGF BB) and neural factor protein pathway 9 (NEDD9). The activation of these signaling pathways requires the formation of *C. albicans* hyphae and the expression of Als3 adhesin. The second mechanism is active penetration. The hyphae of *C. albicans* elongate to penetrate epithelial cells. Both processes, endocytosis and active penetration, can occur at the same time (Swidergall and Filler, 2017).

C. albicans can also penetrate epithelial cells by a paracellular route. It does this by secreting extracellular hydrolytic enzymes into the local environment (Swidergall and Filler, 2017; Lewis and Williams, 2017; Vila et al., 2020). These hydrolytic enzymes facilitate the adherence to oral epithelium, the rupture of intercellular junctions and the invasion of oral mucosa evading host defenses (Wibawa, 2016). These enzymes include:

- *Secreted aspartyl proteinases (SAPs)*. One of the most studied groups of *C. albicans* hydrolytic enzymes are SAPs that degrade E-cadherin and other proteins that hold epithelial cells together (Wibawa, 2016; Swidergall and Filler, 2017; Lewis and Williams, 2017; Vila et al., 2020). This group consists of 10 proteins from Sap1 to Sap10. SAPs increase adherence, headline damage and evasion of host defense (Hube and Naglik, 2001). *C. albicans* can also stimulate calpain in epithelial cells, which is a cysteine protease that degrades E-cadherin (Swidergall and Filler, 2017). Although the function of SAPs is not entirely clear, it seems that these proteins provide the nutrition for the yeast cells, allowing *C. albicans* to continue to penetrate and invade the tissues.
- *Phospholipases (PLs)*. PLs hydrolyze certain phospholipids in the cell membranes, thus destabilizing them. Therefore, these enzymes collaborate in the tissue invasion and in the acquisition of nutrients (Wibawa, 2016; Lewis and Williams, 2017; Vila et al., 2020).

- **Hemolysins.** Another virulence factor of the genus *Candida* is the production of hemolysins. These enzymes allow the fungus to obtain iron from the host tissues that it uses for growth, metabolism and invasion. For this purpose, *C. albicans* is able to bind to erythrocytes and subsequently obtain iron from them (Wibawa, 2016).

Evasion to the host immune responses

The patient with OC tries to defend himself by producing an innate and adaptive immune response. The innate response is the first line of defense, it is non-specific and broad. It includes complement system and cells such as neutrophils and macrophages. However, the adaptive immune response is specific because it recognizes *Candida* antigens (Wibawa, 2016). Immunosuppression can encourage the invasion of *Candida* species and damage. There are many immunosuppressed patients, such as intensive care hospital patients, patients with neutropenia, HIV/AIDS patients and patients receiving immunosuppressive drugs in which the immune response against *C. albicans* may not work properly (Hube and Naglik, 2001). However, in immunocompetent patients the cells secrete antimicrobial peptides that destroy *C. albicans* and release pro-inflammatory cytokines that cause neutrophils to migrate to the area, eliminating *C. albicans* (Swidergall and Filler, 2017).

Even so, *C. albicans* has a number of virulence factors that help it evade host defenses. For example, SAPs proteinases are able to destroy immune system molecules such as antimicrobial peptides and antibodies. Another factor that favors the evasion of host defenses is candidalysin that is a cytolytic peptide toxin. Candidalysin is considered a true virulence factor of *C. albicans* and is important in both mucosal and invasive infections (Vila et al., 2020; Swidergall and Filler, 2017; Naglik et al., 2019).

Host defense peptides (HDP) are the first line of defense against fungal infections. Epithelial cells release multiple types of HDP such as β -defensins and cathelicidins that destroy or slow down the growth of *C. albicans*. HDPs act by different mechanisms that target the fungal cell membrane and the mitochondria. *C. albicans* is able to evade the effects of HDPs by releasing Msb2, a mucin-like membrane protein, which inactivates HDPs and secretes SAPs, which break down HDPs (Saraswat et al., 2016). It also releases FLU1 efflux pump which reduces intracellular HDPs levels (Swidergall and Filler, 2017).

The continuing exposure to HDPs creates a stressful response in *C. albicans*. Activation of the high-osmolarity-glycerol (HOG) pathway allows *C. albicans* to resist histatin 5 and human β -defensins 2 and 3. The RNA-binding protein SSD1 acts in part through the transcription factor Bcr1 to mediate resistance to human β -defensin 2 (Gank et al., 2008). The activation of the mitogen-activated protein kinase Cek1 (MAPK) improves the surface exposure of β -1,3-glucans, raising the uptake of histatin 5 and increasing the sensitivity to HDPs (Swidergall and Filler, 2017).

Predisposing factors to OC

There are different risk factors (Table 2) that have been associated with the presence of OC. Among them, are systemic factors such as age (elderly and infants populations), primary and secondary immunosuppression, the use of systemic corticosteroids, diabetes mellitus, active malignancies, radiotherapy, chemotherapy, anemia, the use of antibiotics, Cushing's syndrome, malnutrition, and the use of drugs that reduce salivary flow (Bandara and Samaranayake, 2019; Bugshan et al., 2017; Hellstein and Marek, 2019; Hoare et al., 2017; Lombardi and Ouanounou, 2020; Swidergall and Filler, 2017; Williams and Lewis, 2011). On the other hand, there are a number of local factors that have classically been associated with OC such as the use of dentures, poor denture and oral hygiene, hyposalivation, the use of topical corticosteroids and steroid inhalers, high carbohydrate diet and smoking (Bandara and Samaranayake, 2019; Bugshan et al., 2017; Lombardi and Ouanounou, 2020). The most important risk factors associated with the development of OC will be reviewed below.

Table 2 Risk factors of oral candidiasis.

Systemic factors	Local factors
Age (elderly/infants)	Use of dentures
Immunosuppression	Poor oral hygiene
	Poor denture hygiene
Use of systemic corticosteroids	Use of topical corticosteroids
Diabetes Mellitus	Use of steroid inhalers
Malignancies	High carbohydrate diet
Head & Neck radiotherapy	Smoking
Chemotherapy	Hyposalivation
Use of antibiotics	
Malnutrition	
Drugs-induced dry mouth	

Age

Age is a risk factor for OC. It has been observed that OC often appears at extreme ages in life, such as infants and elderly (Vila et al., 2020). OC often occurs in older patients, because this group of patients suffers from a greater number of comorbidities, such as diabetes, which increases the risk of OC. In addition, the elderly take a lot of drugs which produce hyposalivation, increasing the risk of OC. In addition, they sometimes wear dentures to replace lost teeth and do not have proper oral hygiene (Bianchi et al., 2016). In children, the prevalence of OC varies between 4% and 15%. *C. albicans* colonizes the newborn through the birth canal or the environment (Vainionpää et al., 2019; Telles et al., 2017).

Immunosuppression

C. albicans can change from commensal to pathogenic altering oral biofilm when immunosuppression is present. These alterations may in turn increase the resistance of *Candida* species to antifungal treatment favoring systemic infections (Hellstein and Marek, 2019). There are different diseases and treatments that can cause immunosuppression. Among them are HIV/AIDS, the use of immunosuppressants, chemotherapy, use of immunomodulators, graft-versus-host disease and agranulocytosis (Vila et al., 2020).

Before the introduction of antiretroviral therapy, OC was very common in HIV/AIDS patients. In fact, the presence of oropharyngeal candidiasis is considered a predictor of HIV disease progression (Telles et al., 2017). Nowadays, OC is the most frequent oral lesion in HIV patients. In addition, it has been described how these patients are more likely to suffer from candidiasis caused by other *Candida* species such as *C. dubliniensis*. HIV patients also have fewer antimicrobial protective factors such as histatin 5. In addition, HIV patients suffer highly drug resistant, mainly to fluconazole (Vila et al., 2020; Ramirez-Amador et al., 2020).

In renal transplant patients, OC has been described as the most frequent oral lesion. It has also been observed that in the immediate post-transplant period the risk of OC is higher, probably due to the higher dose of immunosuppressive treatment in this period (Lopez-Pintor et al., 2010, 2013). There are currently other patients receiving immunosuppressive treatments for rheumatological diseases or chronic inflammatory diseases. In these patients, OC can also appear. There are studies carried out in patients with antineutrophil cytoplasmic antibody-associated vasculitis who received treatment with cyclophosphamide, rituximab or other immunosuppressants, in addition to corticoids, which showed how OC was a predictor of subsequent severe infections, due to a decrease in the immune response (Yamaguchi et al., 2019).

Head & neck radiotherapy and chemotherapy

It has been observed that patients who are treated with head & neck radiotherapy often suffer from OC. According to certain studies, the presence of OC is more frequent in those patients with a low leukocyte count, those who suffer from oral mucositis and who have a lower salivary flow (Nishii et al., 2020). Similarly, patients who were treated in the past with head & neck radiotherapy suffer from chronic hyposalivation and therefore from OC. In these patients, it has been observed that not only does the colonization of *C. albicans* increase, but also that of other species such as *C. glabrata* and *C. tropicalis* (Tarapan et al., 2019).

The incidence of OC varies between 20% and 40% in patients treated with chemotherapy, depending on the treatment, dose and duration. Patients who receive this treatment due to hematological malignancies suffer a higher incidence of OC (Diaz et al., 2019).

Diabetes

There are studies that have shown how patients with diabetes mellitus are more frequently colonized by *C. albicans*, so they frequently suffer from OC. There are studies that showed an association between poorer glycemic control and higher *Candida* load (Zomorodian et al., 2016). Diabetic patients are also more prone to OC if they wear dentures (Gonzalez-Serrano et al., 2016). It has also been observed how these patients have a higher prevalence of *C. dubliniensis*, and how strains isolated from patients with diabetes are more resistant to antifungal treatments (Zomorodian et al., 2016).

Use of antibiotics, systemic steroids, and other treatments

The use of broad-spectrum antibiotics is one of the factors most associated with the appearance of OC. The decrease of the bacterial flora causes alterations in the levels of *Candida*, favoring its proliferation (Vila et al., 2020; Farah et al., 2010; Shenoy and Gottlieb, 2019).

In the same way, systemic steroids also encourage the development of OC. This is due to their immunosuppressive effect and to adverse effects such as hyperglycemia (Shenoy and Gottlieb, 2019).

The use of IL-17 blockers also promotes the development of candidiasis. Examples of these drugs are brodalumab, ixekizumab and secukinumab. These drugs are used in rheumatological and dermatological conditions such as ankylosing spondylitis and psoriasis (Shenoy and Gottlieb, 2019).

Nutritional disorders

There are a number of nutritional alterations that have been linked to the appearance of OC. A high-carbohydrate diet and hematic deficiencies should be highlighted. Also, deficiencies of iron, magnesium, zinc, folic acid, selenium and vitamins B12, B6, A and C have been linked to OC (Vila et al., 2020).

Use of steroid inhalers

Steroid inhalers used to treat asthma, such as fluticasone, increase the risk of OC (Shenoy and Gottlieb, 2019). This is due to local decrease in cellular immunity and phagocytosis (Telles et al., 2017).

Reduced salivary flow

The decrease in salivary flow favors the appearance of OC. Saliva is one of the first lines of defense against *Candida* and contains different agents with antifungal effect such as defensins, lysozymes, IgA, mucins, calprotectin, histatin 5, lactoferrin and lactoperoxidase, among others (Hoare et al., 2017; Telles et al., 2017). In addition, a correct salivary flow prevents *Candida* overgrowth due to its washing effect (Hoare et al., 2017). Therefore, when the saliva decreases, the washing effect and the antifungal components are reduced. The incidence of salivary alterations increases not only in elderly patients (mostly due to the use of drugs) but also in other patients such as those receiving chemotherapy, radiotherapy, and HIV patients (Vila et al., 2020).

Patients with Sjögren's syndrome are at increased risk for OC. In fact, there are studies that showed how OC is the most frequent lesion in patients with primary Sjögren's syndrome (Billings et al., 2017; Serrano et al., 2020a). In these patients, it has been shown how the colony forming units of *C. albicans* increase when the salivary flow decreases (Serrano et al., 2020b).

Use of dentures and other oral appliances

As already shown above, *C. albicans* is able to adhere to the surface of dentures and to form biofilms in them. The prolonged use of dentures, in addition to poor hygiene and continued trauma favors the emergence of OC. Dentures are in themselves a favorable environment for the growth of *Candida*: it avoids the presence of saliva, acid pH and low amount of oxygen which promotes SAPs. In immunosuppressed patients who are denture wearers, the appearance of denture stomatitis is more frequent. The material of the denture is also important, acrylic dentures favor the appearance of candidiasis more than metallic ones. Orthodontic appliances also favor their emergence (Vila et al., 2020). In addition, angular cheilitis is more frequent in patients with dentures, due to the loss of vertical dimension in patients wearing dentures for many years. In these cases, the corners of the mouth are moist, which favors *Candida* and *Staphylococcus* infections (Telles et al., 2017).

Use of topical steroids

Treatment with topical steroids, frequently used in patients with chronic inflammatory and autoimmune oral diseases, has also been associated with the appearance of OC. These treatments generate local immunosuppression and alter the oral environment. These alterations usually revert when treatment ceases. In cases where treatment with topical steroids will be of long duration, prophylactic antifungal treatment is recommended (Vila et al., 2020; Tejani et al., 2016; Marable et al., 2016).

Smoking

Patients who smoke have higher levels of *Candida*, which increases the risk of OC. This is mainly due to a reduction of salivary flow from tobacco. This leads to a lower pH, reduces IgA and depresses neutrophil function, which promotes the appearance of OC (Vila et al., 2020). There is a lack of information regarding e-cigarettes and the appearance of OC. However, in vitro studies have shown how these devices induce the genes of virulence factors SAP2, SAP3 and SAP9 (Vila et al., 2020; Sultan et al., 2018).

Clinical presentations of oral candidiasis

It is unknown why different forms of OC are produced by the same fungal species. Nor is it known why a subject can present one clinical form of candidiasis and not another. What is understood is that *C. albicans*, which is the most frequently detected agent, is a genotypically and phenotypically heterogeneous species what could explain these variations (Lewis and Williams, 2017). OC can be divided into three categories: pseudomembranous, erythematous and hyperplastic forms. In addition, there are a number of multifactorial lesions associated with *Candida* such as denture stomatitis, angular cheilitis and linear gingival erythema. Below, the clinical forms of oral candidiasis will be reviewed (Table 3).

Table 3 Clinical presentations of OC.

<i>Clinical presentations of OC</i>	
Acute erythematous candidiasis	• Located in the dorsum of the tongue which present as depapillated. • Can be asymptomatic, sometimes associated with sensitivity to certain foods. • Related to treatment with antibiotics. • Other risk factors: steroid therapy, immunosuppression.
Pseudomembranous candidiasis	• Creamy white plaques that can be removed by gently scraping, showing an underlying erythematous mucosa. • Can be asymptomatic or cause tenderness, burning sensation and dysphagia. • Risk factors: immunosuppression, neonates, elderly and patients under steroid treatment.
Chronic hyperplastic candidiasis	• Uncommon form of OC. • White lesions, often asymptomatic, on the dorsum or lateral of the tongue, commissural angles, or the anterior buccal mucosa. • Risk factors: Middle-aged to older males and smokers. • Clinical forms: homogeneous or heterogeneous.
Angular cheilitis	• Secondary form of OC. • Red lesions ulcerated or fissured at the commissural angles of the mouth. • Risk factors: decrease in vertical dimension, constant humidity, a deficiency in iron and B12 vitamin. • Sometimes associated to other species: <i>Staphylococcus aureus</i> or streptococcus.
Median rhomboid glossitis	• Secondary form of OC. • Symmetrical shaped lesion in the dorsum of the tongue, usually asymptomatic. • Risk factors: smokers or use of steroid inhalers.
Denture stomatitis	• Asymptomatic, sometimes causes pain or burning sensation. • Under dentures, more frequently on the hard palatal, showing a red mucosa beneath the fitting surface. • Risk factors: poor oral hygiene, not removing the denture or when they are deteriorated or not well adapted dentures.
Chronic mucocutaneous candidiasis	• Secondary form of candidiasis. • Superficial infections of the skin, eyes, mouth, nails, and other mucous membranes. • It can appear as angular cheilitis or hyperplastic candidiasis. • Risk factors: impaired immune function, endocrinopathies, autoimmune diseases.

Erythematous candidiasis

This form of OC usually appears after a treatment with broad spectrum antibiotics, due to the reduction in the levels of the bacteria forming the oral microflora. Some other predisposing factors as steroid therapy specially inhale steroids, and immunosuppressants may also contribute to local immunosuppression and therefore to the overgrowth of *Candida* (Lewis and Williams, 2017; Williams and Lewis, 2011). Although it is frequently asymptomatic, it can appear as a painful bright erythematous lesion, usually located in the dorsum of the tongue (Fig. 1). The tongue may present as depapillated and sometimes is associated with sensitivity to certain foods (Lewis and Williams, 2017; Bandara and Samaranayake, 2019; Hellstein and Marek, 2019). Usually, once the antibiotic intake is completed, this type of lesions will resolve without any need of additional treatment. When chronic forms of erythematous candidiasis appear, mirror images may appear, with lesions on the dorsum of the tongue and the hard palate (Lewis and Williams, 2017).

Fig. 1 Candidiasis erythematous in a patient who was treated with amoxicillin for a week for a dental infection.

Pseudomembranous candidiasis

Pseudomembranous candidiasis (also known as oral thrush) is characterized by the appearance of creamy white plaques in the oral mucosa (Fig. 2) that can be easily removed by gently scraping them, showing an underlying normal or erythematous mucosa (Williams and Lewis, 2011; Lewis and Williams, 2017; Lombardi and Ouanounou, 2020). This clinical form frequently appears in immunosuppressed patients, neonates, elderly and patients under steroid treatment (specially inhaled corticosteroids), and it could be acute or chronic. It can present at different parts of the oral cavity as the palate, oropharynx, dorsal tongue, or the buccal mucosa. It could be either asymptomatic or it may course with tenderness, burning sensation or dysphagia (Lombardi and Ouanounou, 2020). In case of using inhaled corticosteroids, patients should be instructed to rinse their mouth with water after using the inhaler to prevent this condition (Lewis and Williams, 2017). The lesions contain fungal hyphae, bacteria, desquamated epithelial cells, keratin, fibrin and inflammatory cells (Lombardi and Ouanounou, 2020).

Chronic hyperplastic candidiasis

Chronic hyperplastic candidiasis (CHC) is a less common type of candidiasis. It presents as a white lesion, often asymptomatic, which cannot be removed by gently scraping. It appears most frequently at the commissural angles, the anterior buccal mucosa, and on the dorsum or lateral of the tongue. It usually affects middle-aged to older males and smokers. There are two clinical forms: homogeneous CHC (Fig. 3) when having smooth and white lesions, or heterogeneous CHC (Fig. 4) when appear erythematous areas accompanied with the white lesions (Lewis and Williams, 2017; Hellstein and Marek, 2019; Lombardi and Ouanounou, 2020). It has been proposed that this type of OC could develop epithelial dysplasia (especially in heterogeneous CHC or speckled lesions) and may progress to oral cancer. Therefore, it has been recommended to treat this type of lesions with antifungals prior taking a biopsy (Lewis and Williams, 2017; Lombardi and Ouanounou, 2020). If the antifungal therapy is not enough for resolving the lesion, a biopsy must be taken and a histopathological study should be carried out in these cases (Hellstein and Marek, 2019; Lombardi and Ouanounou, 2020).

Fig. 3 Chronic hyperplastic candidiasis in a smoking patient.

Fig. 4 Chronic hyperplastic candidiasis of speckled appearance in a patient who smoked 20 cigarettes a day.

Angular cheilitis

Angular cheilitis is considered a secondary form of OC. It appears as red lesions, ulcerated or fissured, at the commissural angles of the mouth which typically causes soreness and pain (Fig. 5). Several predisposing factors are related. Among them are decrease in vertical dimension which result in keeping constantly humid this area, and iron and B12 vitamin deficiencies. Angular cheilitis can present as an isolated lesion, or with concomitant intraoral candidiasis, and sometimes other species as *Staphylococcus* or *Streptococcus* may be also present (Lewis and Williams, 2017; Bandara and Samaranayake, 2019; Hellstein and Marek, 2019; Lombardi and Ouanounou, 2020; Vila et al., 2020).

Median rhomboid glossitis

Median rhomboid glossitis is also considered a secondary form of OC. It presents as a symmetrical shaped lesion in the middle of the dorsum of the tongue anterior to the circumvallate papilla (Fig. 6). Lesions are atrophic and erythematous, due to the loss of filiform papilla. It usually courses with no symptoms and appears in patients who smoke or use steroid inhalers (Lewis and Williams, 2017; Hellstein and Marek, 2019; Lombardi and Ouanounou, 2020).

Denture stomatitis

Denture stomatitis or chronic erythematous/atrophic candidiasis is the most common type of OC. It is usually asymptomatic but sometimes it may cause pain or burning symptoms (Lewis and Williams, 2017; Lombardi and Ouanounou, 2020). It develops under acrylic or metallic dentures, more frequently on the hard palatal than in the alveolar ridge, showing a reddening of the mucosa beneath the fitting surface (Fig. 7). It can be associated with the use of orthodontic appliances. In the literature, three groups of denture stomatitis have been described (Newton's classification). Type I is characterized by small petechial and inflammation, pin-point erythema of the palatal mucosa. Type II presents diffuse erythema in the oral mucosa in contact with the denture, partially or completely. Finally, type III is defined as papillar or granular hyperplasia of the oral mucosa in the middle of the palate or at the alveolar ridges (Lombardi and Ouanounou, 2020; Vila et al., 2020).

Fig. 5 Angular cheilitis in a patient wearing a denture with diminished vertical dimension.

Fig. 6 Median rhomboid glossitis in an asthmatic patient being treated with steroid inhalers.

Fig. 7 Denture stomatitis in a patient wearing an acrylic denture.

Several risk factors are related to this condition, as poor oral hygiene, not removing the denture, deterioration or lack of adaptation. When this happens, *Candida* can colonize the denture (Lombardi and Ouanounou, 2020; Lewis and Williams, 2017). Therefore, it is of great importance to advise on correct oral and denture hygiene. Dentures should be cleaned with a brush/toothbrush and several commercial products for its sanitation, as specific lozenges, hypochlorite if there are no metal components, or chlorhexidine if there are, can be used. It is also important to insist to remove them while sleeping (Lewis and Williams, 2017; Hellstein and Marek, 2019).

Chronic mucocutaneous candidiasis

Chronic mucocutaneous candidiasis is a form of candidiasis which appears in those patients with an impaired immune function. There are cases described in the literature in patients suffering endocrinopathies (Addison disease, hypothyroidism, hypoparathyroidism, and diabetes mellitus), autoimmune diseases and immunosuppressed for different reasons. Certain types of mucocutaneous candidiasis have been described as having a recessive autonomic genetic origin. They are also associated with an altered function or interleukin 17 deficiency (Lewis and Williams, 2017; Lombardi and Ouanounou, 2020; Telles et al., 2017).

It presents with a variety of superficial infections of different parts of the body, as the skin, eyes, mouth, nails, and other mucous membranes. When it affects the oral cavity, it can appear as angular cheilitis or hyperplastic candidiasis (Lewis and Williams, 2017; Lombardi and Ouanounou, 2020; Telles et al., 2017). Mucocutaneous candidiasis has a poor response to antifungal treatment, and this lack of response is related to the level of immunodeficiency (Lombardi and Ouanounou, 2020).

Linear gingival erythema

Linear gingival erythema is a *Candida*-associated lesion that has been described in HIV patients. It is characterized by linear erythematous lesions affecting the gingiva of the anterior teeth. It may not be accompanied by symptoms but in other patients it may be associated with discomfort and bleeding. It is believed to be due to subgingival colonization of *Candida* species in patients with an inadequate activity of polymorphic nuclear neutrophils. This lesion has been described as a predictor of

immunosuppression in these patients (Goncalves et al., 2013). Its possible association with *C. albicans* has always been controversial and currently due to the use of retroviral therapy its incidence has decreased considerably (Ryder et al., 2020).

Other non-Candida-associated oral fungal lesions

Other fungal infections (Table 4), much less frequent than OC, which can occur with oral lesions, are described below. These infections usually appear in immunosuppressed patients.

Aspergillosis

Aspergillosis is the second most prevalent fungal infection. In cases of maxillary sinus infection by *Aspergillus* the most common species isolated is *Aspergillus fumigatus* (Bandara and Samaranayake, 2019; Maschmeyer and Ruhnke, 2004; Bugshan et al., 2017). *Aspergillus flavus* is related to invasive infection (Bugshan et al., 2017). This type of infection often occurs in hospitals and in places where there may be a lack of hygiene. It can also appear in immunosuppressed patients (Bandara and Samaranayake, 2019; Maschmeyer and Ruhnke, 2004). In the oral cavity, it has been described how *Aspergillus* can enter through the marginal gingiva or the gingival sulcus. It has been associated with painful yellow or white gingival ulcers. It can also lead to grey or purple swellings of the soft tissues. The most common oral locations of these infections are the palate or posterior tongue (Bandara and Samaranayake, 2019; Maschmeyer and Ruhnke, 2004). It can be confused with allergic-type sinusitis when it affects the maxillary sinus giving rise to an aspergilloma or mass formed by the hyphae (Bugshan et al., 2017). *Aspergillus* hyphae can invade the oral mucosa and lead to systemic infections (Bandara and Samaranayake, 2019; Maschmeyer and Ruhnke, 2004).

Histoplasmosis

Histoplasmosis is caused by *Histoplasma capsulatum*, which is found in warm, humid environments, and in places where there are bird and bat excreta, as well as where soils are high in nitrogen (Bandara and Samaranayake, 2019; Hernández et al., 2004). It is the most common systemic fungal infection in the United States. Transmission of the disease often occurs through airborne spores from the mycelial form (Bugshan et al., 2017; Hernández et al., 2004). It usually affects more men than women. It often occurs in immunosuppressed patients (Bandara and Samaranayake, 2019; Hernández et al., 2004). Histoplasmosis is usually accompanied by pulmonary alterations with chest pain, cough, dyspnea and joint pain that usually last between 1 and 2 weeks. When the form is limited it is called primary acute pulmonary form. These alterations can become chronic in older people and smokers. On rare occasions, disseminated histoplasmosis can occur when the microorganism spreads through the bloodstream, especially in immunosuppressed such as AIDS patients, infants and elderly patients (Bugshan et al., 2017; Hernández et al., 2004). It rarely gives oral lesions, the most frequent oral lesion being the ulcerative lesion, but it can also be associated with papular, nodular or granulomatous lesions. Lesions have been described on the tongue, buccal mucosa, palate, gingiva and lips (Bandara and Samaranayake, 2019; Hernández et al., 2004). When ulcerous lesions appear, a differential diagnosis must be made with oral squamous cell carcinoma (Bugshan et al., 2017; Telles et al., 2017).

Cryptococcosis

Cryptococcosis is an infection caused by *Cryptococcus neoformans* in immunosuppressed patients and by *Cryptococcus gattii* in immunocompetent patients. *C. neoformans* is found in the soil and feces of birds such as canaries, parrots and pigeons. *C. gattii* is endemic to Australia and is found in the koala bear. *Cryptococcus* is the most common cause of meningitis in southern Africa. Like other fungal infections it appears in immunocompromised patients such as HIV patients, patients on immunosuppressive therapy and cancer patients. It can also appear in smokers. Oral lesions associated with cryptococcosis can present as purple nodules of granulation tissue, swelling and ulcers. They can appear on the palate, gingiva and in the tooth socket after extraction. Sometimes the ulcerated lesions associated with Cryptococcosis can be indurated (Bandara and Samaranayake, 2019; Telles et al., 2017).

Coccidioidomycosis

Coccidioidomycosis is caused by *Coccidioides immitis*. It is called valley fever, as it appears in the soil of the southwest part of the United States, Mexico and Central and South America. It affects people over the age of 60. As in other cases, its incidence is higher in immunosuppressed patients such as AIDS and HIV patients, transplant patients, patients treated with immunosuppressors, diabetic patients and pregnant women. Oral lesions are rare; if they appear, they are presented as ulcerated granulomatous nodules and non-specific ulcers (Bandara and Samaranayake, 2019; Telles et al., 2017).

Table 4 Characteristics of fungal infections other than candidiasis.

Fungal Infection	Causative agents and epidemiology	Risk factors	Oral lesions	Diagnosis	Treatment
<i>Aspergillosis</i>	- 2nd most prevalent - Most common species isolated <i>Aspergillus fumigatus</i> (sinus infection) and <i>Aspergillus flavus</i> (invasive infection)	- Immunosuppression - Hospitalization - Lack of hygiene - Dental extraction	- Gingival ulcers - Swellings of the oral mucosa - Fungal sinusitis (mass or aspergilloma in the maxillary sinus) - Can lead to systemic infections	- Culture - Serology (antigen galactomannan) - PCR - Biopsy - Limulus assay	- Antifungal treatment: amphotericin B, voriconazole, posaconazole, itraconazole, and caspofungin. - Debridement of aspergilloma in maxillary sinus
<i>Histoplasmosis</i>	- Caused by <i>Histoplasma capsulatum</i> - Men are more affected - Most common systemic fungal infection in United States	- Immunosuppression - Warm and humid environments - Bird and bat excreta - Soils high in nitrogen	- Rare - Ulcerative lesion - Papular, nodular or granulomatous are also described	- Clinical - Biopsy - Culture - Serology (immunodiffusion, histoplasmin skin test, complement fixation test) - PCR (Polymerase chain reaction)	- Improve immunocompetence - Antifungal therapy: amphotericin B (drug of choice), itraconazole and ketoconazole
<i>Cryptococcosis</i>	- <i>Cryptococcus neoformans</i> present in the soil and feces of birds. It affects immunosuppressed patients - <i>Cryptococcus gattii</i> endemic to Australia. It affects immunocompetent patients	- Immunocompromised patients - Smokers	- Purple nodules of granulation tissue, swelling and ulcers (sometimes indurated) - Affect palate, gums and tooth socket after extractions	- Isolation of the pathogen in blood, sputum or bronchoalveolar samples in pulmonary and disseminated infections - Biopsy - Serology (circulating antigens on serum)	- Systemic antifungals: amphotericin B, flucytosine, fluconazole
<i>Coccidioidomycosis</i>	- <i>Coccidioides immitis</i> - <i>Coccidioides posadasii</i> - Southwest of the United States, Mexico and Central and South America	- >60 years - Immunosuppressed patients - Diabetic patients - Pregnant women	- Ulcerated granulomatous nodules - Non-specific ulcers	- Clinical presentation - Biopsy - Serology - Coccidioidin skin test	- Systemic antifungals: fluconazole, amphotericin B, ketoconazole and itraconazole
<i>Blastomycosis</i>	- <i>Blastomyces dermatitidis</i> - North, Central, and South America	- Immunocompromised patients - Forest areas	- Ulcerous lesions - Granulomatous or verrucous lesions	- Clinical - Biopsy - Serology - Coccidioidin skin test	- Systemic antifungals: fluconazole, amphotericin, ketoconazole and itraconazole
<i>Mucormycosis</i>	- <i>Rhizopus arrhizus</i> - Spread by inhaling spores or through wounds	- Immunocompromised patients (diabetes patients)	- Swelling of maxillary ridge or the palate due to maxillary sinus affection	- Biopsy - Culture	- Surgical debridement - Systemic antifungals: amphotericin B
<i>Geotrichosis</i>	- <i>Geotrichum candidum</i> - Present in soil, fruits, plants, and vegetables	- Immunocompromised patients (HIV/AIDS, diabetes mellitus, malignancies, used of steroids or long-term antibiotic treatment, advanced age)	- <i>Candida albicans</i> like lesions	- Culture - Microscopic examination	- Topical antifungals: nystatin and gentian violet - Systemic: voriconazole and amphotericin B

Blastomycosis

Blastomycosis is caused by *Blastomyces dermatitidis*. It appears in North, Central, and South America. In addition to immunocompromised patients, it can appear in forest areas (farmers and hunters). In the oral cavity it can lead to ulcerous lesions and granulomatous or verrucous lesions (Bandara and Samaranayake, 2019; Telles et al., 2017).

Mucormycosis

Mucormycosis is mainly caused by *Rhizopus arrhizus*. But it can also be produced by *Rhizopus microsporus*, *Rhizopus stolonifer*, *Mucor circinelloides*, *Mucor velutinosus*, among other species. It is usually spread by inhaling spores or through wounds. Like candidiasis, it is an opportunistic infection and is more common in immunocompromised patients. Blood vessels involvement may lead to embolism, resulting in necrosis of the affected tissue. The sinus, lungs and brain structures can also be affected. If the maxillary sinus is affected, it can lead to intraoral swelling on the maxillary ridge or the palate, which if not treated correctly can cause necrosis (Bugshan et al., 2017; Telles et al., 2017).

Geotrichosis

Geotrichosis is another opportunistic infection caused primarily by *Geotrichum candidum*. It produces similar lesions to OC and therefore it is often misdiagnosed. This fungus is found in plants, vegetables, fruits and soil. Normally, it is not pathogenic but in people with immunodeficiencies it can lead to invasive diseases (Telles et al., 2017).

Diagnosis of oral fungal lesions

Anamnesis

Diagnosis of OC is usually made with a complete and guided medical history and the clinical examination findings. It is important to take into account that several risk factors have been related to the presence of *Candida* infections, such as poor oral hygiene, impaired salivary gland function, denture use and associated conditions as diabetes, xerostomia, tobacco use, immunosuppression (HIV-infection, leukemia, solid organ transplantation) or medication as antibiotics, corticosteroids, psychotropics or immunosuppressives.

Clinical diagnosis

As previously mentioned, there are multiple clinical forms of OC, either as acute or chronic lesions, which may appear in more than one location at the same time. The dentist should look for any clinical signs and symptoms that patients suffering from OC may experience. The range of symptoms varies from being in some cases asymptomatic to experiencing superficial signs (as itching, burning or soreness). In more severe cases, fever or tachycardia could be present (Vila et al., 2020; Telles et al., 2017). A differential diagnosis with other white lesions (chemical burn, frictional keratosis, leukoplakia or dysplasia) should be carried out for chronic hyperplastic candidiasis. For diagnosing pseudomembranous candidiasis, the white lesions are wiped off by gentle scraping them, showing an underlying normal or red mucosa. When observing erythematous candidiasis, other possible erythematous lesions should be ruled out such as erythroplakia, iron or vitamin B12 deficiency and thermal burns (Bandara and Samaranayake, 2019; Bugshan et al., 2017). In most cases the clinical aspect together with the symptomatology and associated risk factors are sufficient to make a presumptive diagnosis. The diagnosis can also be made by the response to antifungal therapy (Telles et al., 2017).

Culture

Different methods for collecting *Candida* from the oral cavity can be used, including swab, oral rinse and imprint. One of the most widely used is the plain microbial swab that can be applied directly to the lesion and sent for culture. Samples are inoculated onto Sabouraud dextrose agar and incubated at 37 °C for 24–48 h and the results are expressed as *Candida* colony forming units per ml (CFU/mL). There are also chromogenic media, which allow to differentiate the growth of the different species of *Candida* according to the color and appearance of the colonies (Lewis and Williams, 2017). These techniques are frequently enough for the identification of *Candida* from those cases of erythematous and pseudomembranous candidiasis. Nevertheless, it should be noted that since *Candida* is part of the commensal microbiota of healthy population, its simple identification does not mean infection (Lombardi and Ouanounou, 2020). This techniques have a low sensitivity and in addition, it can lead to false-positive results (Bhattacharya et al., 2020).

Cytology

Exfoliative cytology is another technique that could be used for the identification of *Candida*, especially in those cases of pseudomembranous candidiasis. A periodic acid-Schiff staining is used for detecting fungal pseudohyphae. This technique is

non-invasive, cost effective and simple. However, again, the identification of *Candida* does not prove tissue invasion (Lombardi and Ouanounou, 2020; Hellstein and Marek, 2019; Bugshan et al., 2017). This technique provides information about the prevalence of fungal organisms (Hellstein and Marek, 2019). There are cases where a microscopic study with ethylene blue staining or with 10% potassium hydroxide can also be performed. These stains show the yeasts, hyphae and pseudohyphae, but do not show the invasion of the tissues (Lombardi and Ouanounou, 2020).

Hematological test and sialometry

A hematological test should be checked, especially values of full blood count, ferritin, vitamin B12 and folate. In diabetic patients, blood glucose and glycated hemoglobin (HbA1c) need to be measured (Lombardi and Ouanounou, 2020; Lewis and Williams, 2017; Telles et al., 2017). The performance of a sialometry will help to check if the patient has a reduced salivary flow, which as we have shown is associated with the appearance of OC.

Biopsy

In most cases of *Candida* infection, a biopsy is not needed. Nevertheless, when hyperplastic candidiasis is present and has not respond to antifungal therapy, a tissue biopsy is indicated, for confirming the invasion of the epithelium by *Candida*. In these circumstances, an acid-Schiff (PAS) technique is regularly used (Bandara and Samaranayake, 2019; Lewis and Williams, 2017). In the tissue, it can be observed hyperkeratosis of the epithelium with elongation of rete ridges and chronic inflammation in the connective tissue (Bugshan et al., 2017). This test also serves to rule out the possible presence of dysplasia or malignancy (Telles et al., 2017).

The biopsy is also indicated in cases of ulcerous and granulomatous lesions produced by histoplasmosis and other fungi. In these cases, granulomatous inflammation is observed accompanied by plasma cells, multinucleated giant cells, macrophages and lymphocytes (Bugshan et al., 2017).

Other diagnostic tools

Molecular methods can be used to identify different species of *Candida* with species-specific polymerase chain reaction (PCR). This technique is very useful in refractory lesions and research studies (Lombardi and Ouanounou, 2020; Lewis and Williams, 2017; Hernández et al., 2004). Although these tests are frequently used for viral and bacterial infections, in the case of fungal infections their use is still limited (Sanguinetti et al., 2019).

Today, despite scientific advances, fungal infections are classically diagnosed through morphological analysis using cultures. However, there are other non-culture-based tests such as immunodiffusion (ID), enzyme immunoassays (EIA) and the complement fixation test. For example, aspergillosis can be diagnosed by the detection of serum antigens such as galactomannan and β -1,3 D-glucan. Furthermore, for the diagnosis of *Cryptococcus* infection one of the most reliable serological tests is the detection of *Cryptococcus neoformans* antigens. However, today the most promising tests are the molecular tools such PCR, sequencing and mass spectrometry. These tests are mainly used in invasive infections or in those cases where the diagnosis is difficult (Sodre et al., 2020).

Treatment

Identification and removal of risk factors

Prior to prescribing an antifungal treatment, it is of great importance to recognize and remove any predisposing factor. As it has been previously said, a thorough medical history should be performed. If anemia or vitamin deficits are present, they need to be solved. In the same line, patients should be advised of the importance of having a correct glycemic control. If smoking habit is present, patients should be encouraged to cease the habit. In addition, whenever possible, the use of antibiotics, topical or systemic corticoids and immunosuppressants should be avoided. In patients who use steroid inhalers, it is advisable to rinse their mouths with water after their use (Lombardi and Ouanounou, 2020; Lewis and Williams, 2017; Williams and Lewis, 2011).

Likewise, oral hygiene and proper denture cleansing need to be recommended. It is necessary to give a series of indications such as cleaning the dentures daily after meals, removing the dentures at night and cleaning when necessary with ultrasound the biofilm. In addition, it is necessary to improve retention, stability, fit and occlusion of dentures (Lombardi and Ouanounou, 2020; Telles et al., 2017).

Antifungal treatment

There are four types of antifungal agents (Lewis and Williams, 2017; Lombardi and Ouanounou, 2020; Telles et al., 2017):

- Polyene antifungal agents, which disrupt the cell membranes of the fungus. This group includes nystatin and amphotericin B. These agents bind to the ergosterol in the fungal cell membrane, increasing permeability and leakage of intracellular contents (K^+ , Na^+ , Ca^{2+}) producing cell necrosis. They were the first antifungal agents. They are mainly used topically. Amphotericin B can be used by intravenous route but it produces toxicity and numerous side effects.

- Azole antifungals, which inhibit the synthesis of ergosterol by interference with lanosterol demethylase. They are fungistatic and include miconazole, fluconazole and itraconazole. Miconazole is used topically, but the rest of azole antifungals are used systemically through oral administration. They interfere with warfarin and statins. However, they do not interact with dabigatran. Nowadays, resistance to azole antifungals is frequent.
- Echinocandin antifungals, which inhibit the enzyme β -1,3 D-glucan synthetase, which inhibits the synthesis of the cell wall of the fungus. Among them are anidulafungin, micafungin and caspofungin.
- Pyrimidines antifungals, which disrupt RNA, DNA and protein synthesis of fungus, such as flucytosine.

Below, the most frequently used local and systemic antifungals for the treatment of OC will be reviewed (Table 5).

Local treatment

Topical treatment is the treatment of choice for most cases of OC. Local antifungals have little side effects since their absorption is limited. Therefore, they do not interact with other systemic drugs. There are several topical formulations as tablets, oral suspension, or gels, among others. Nystatin and miconazole should be the first line treatment for OC, due to their efficacy, cost, and little adverse effects. Nystatin is frequently prescribed as oral suspension in doses of 100,000 IU/mL, 4–6 mL four times daily rinses for 2–3 min, or pastilles (100,000 IU, four times a day), both formulations for 7–14 days (Bandara and Samaranayake, 2019; Quindos et al., 2019). Patient should be instructed to not eat or drink for 30 min afterwards. It is important to prolong the treatment at least 48 h after oral symptoms are resolved, to prevent from OC recurrence (Telles et al., 2017).
